The surgeon and particularly the older surgeon will do well to contemplate occasionally his motivations and incentives and revalue anew his rewards. Let him also reaffirm periodically the Hippocratic Oath! When long years ago this writer was confirmed in the faith of his fathers the preacher employed on the occasion a text from the prophet Jeremiah: 'Stand ye in the ways and see, and ask for the old paths, where is the good way and walk therein and ye shall find rest for your souls.' an instruction equally as important for surgeons as well as for Sunday school communicants. Can there be greater rewards than the satisfaction and the peace of mind which come from having served his fellow man well? Our yoke of duty and responsibility may be heavy but whose opportunity and privilege to bring happiness to others is greater?

The Federated Surgical Society of America
The Regents of the American College of Surgeons provisioned the avid curiosity and thirst for new found knowledge on the part of the practicing surgeon, when they instituted the Forum on Fundamental Surgical Problems. The continued interest in this type of program by the general surgeon in practice affords ample demonstration of the wisdom of that decision. And as more of America's best young surgeons who went to war return and manifest renewed zeal to contribute to the advancement of surgical knowledge an even more critical selection of papers for presentation can be assured. The time is now ripe for the formation of the Federated Surgical Society of America embracing all the ancillary surgical specialties much in the manner of the Federated Biological Societies in the pre-clinical divisions of medicine. That society serves medicine in a unique manner. A similar organization of surgery and its various surgical specialties employing the prototype of the Surgical Forum as its pattern would lend renewed emphasis to the importance of re-

search in surgery. At the same time, it would constitute an important agency in giving better integration to the many now somewhat distinct, branches of surgery. Is not the American College of Surgeons the parent society which should foster this development?

Have surgical meetings had any influence on your intellectual growth and development? They have on mine. Man cannot lift himself up by his bootstraps neither can surgical societies increase surgical knowledge save in so far as they encourage an interchange of ideas between surgeons at the best possible level. Surgical specialists in the same field are not long the best company for one another. There is not enough stimulating sustenance in that type of association for continued growth and development no matter how interesting the interlude provided by such exchanges. The life-giving spirit and vitalizing influence derived from close association with fellow colleagues in the broad domain of medicine is indispensable for the surgeon.

Surgery is on the move. We respect the traditions of the past but the empiricism of surgeons of generations just past is being displaced by the appreciation of and more frequent employment of the scientific method. The touchstone of the scientific method lies in the universal validity of its results. It affords a finality which sets aside all room for continued speculative rationalization. While we are debating and airing our respective opinions on a controversial subject some enterprising individual constructs and carries out the crucial experiment which reveals the truth in the matter. How sterile and unprofitable are discussions based solely on impressions no matter who the authority. Not even the experienced investigator makes a ten strike each time he sets up an experiment. No the progress of research is slow. Yet fact correlated with fact builds a structure which will stand against the winds of time.

It is from the lips of men who are engaged in the exciting pursuit of fact finding that we may expect that stimulating refreshment which makes us better surgeons for the experience. The acquisition of knowledge is not a passive process. List - ing to the recital of the train of events which led up to an im-

portant discovery does not make us better surgeons. It does however make us want to be better and serves to reorient us with reference to the great superiority of the experimental method over empiricism. When all surgeons learn to ask What is the evidence rather than who employs a certain procedure, then the absorptive capacity of surgeons for new found information will have been enhanced considerably. Surgery will profit immensely by having all surgeons listen to expositions in which the experimental method is employed. Moreover young men prosecuting original researches have a right to be heard. And is it not a bit wearisome to have to listen to parrots of other men's thinking?

Unnecessary surgery. Some of my colleagues who are not surgeons tell me that some surgeons perform unnecessary operations and undertake necessary operations which they are not trained to do for pecuniary gain. This is difficult for me to believe. If there be such men in our profession who call themselves surgeons, God have mercy on their souls! Is not the path of the well trained surgeon intent on doing the very best of which he is capable beset with difficulties enough? Can a surgeon take his tasks so lightly that he would submit patients, who seek his counsel to unnecessary or ill advised operations? God forbid! If this be true every man in the profession every hospital in the land should leave no stone unturned to expose such practice. We who enjoy the greatest confidences of patients who place their trust and lives in our hands have a sacred duty to perform. If we knowingly set aside that trust, we are not entitled to the protection which our medical license gives us.

If I forget thee O Jerusalem let my right hand forget her cunning. Steadfastness of purpose and consecrated devotion to his tasks should characterize the resolution of the surgeon in his outlook upon his work.

Surgery is a stern discipline. Surgery is an exacting and stern discipline. Let no man who aspires to be a surgeon be unmindful of this admonition. A realistic, critical attitude of self-analysis by the surgeon with reference to accountability for operative failures and postoperative complications is a *sine qua non* for continued growth and development of the

surgeon and betterment of his accomplishment. The irrepressible optimism of the Pollyannish surgeon denies him the improvement and cultivation which comes from a critical review of every failure. At the base of most disappointments lie errors in judgment or execution some neglect that might have been prevented with adequate forethought and preparation. Only when surgeons have succeeded in eliminating all avoidable causes of death after operation can they be satisfied with their own accomplishment—a laudable but unattainable objective. Yet, the struggle of striving to achieve that which lies beyond our reach makes us better surgeons for the effort. Any record, in which only unavoidable deaths account solely for the mortality, suggests that the surgeon and his associates have done their work well.

Improving the surgical mortality score. A consideration which must be always uppermost in a surgeon's mind is how to reduce the mortality score and at the same time extend the favors of surgery to those patients, who because of age or physical infirmity are not satisfactory operative risks. Familiarity with all the facets of the problem and a studied effort to eliminate or reduce to a minimum all the avoidable causes of death after operation are the items that make for an improved mortality record. In this endeavor the surgeon must exact a high standard of performance from himself as well as from his associates. The day of the one-man operation is over. It takes a trained team of surgeons and nurses, accustomed to working together and alert to the complexities and vagaries of a group of interrelated surgical problems to make a creditable showing. Limitless concern for every detail and precise execution of carefully planned procedures are items out of which success and improvement of the mortality score are compounded.

Preoccupation of mind of the surgeon. Because of the very nature of the cares and heavy responsibilities shared by surgeons, they come to have a certain preoccupation of mind. Try as we may it is not easy to disguise completely our feelings when vexed with anxieties over ill patients. Those who know us best seem to be able to divine our true state of mind. The

cares of patients weigh heavily upon the mind of the surgeon and it is understandable that his spirits may exhibit some of the fluctuations of a barometer contingent upon how the patients under his care are getting on. Who among us has not felt a certain buoyancy of spirit when a very ill postoperative patient takes a turn for the better?

Static character of surgery made dynamic by synthesis of well known facts into new knowledge. This year marks the centenary of the first public demonstration of the employment of anesthesia for operations, one of the most beneficent and welcome gifts to mankind in the history of the world. Antisepsis and asepsis recreated surgery and opened up new and undreamed of avenues for the surgeon's skill. The exclusion of infections from clean wounds gave an impetus to surgery and the entire field of medicine such as it has not experienced since. Surgery bounded forward with a terrific surge. Yet after some years, surgery appeared to have reached an impasse such that, surgeons like the late Lord Moynihan were saying again as surgeons of the preanesthetic and preantiseptic era had said that surgery had reached the acme of its development along technical lines. Yet lesser innovations and a better understanding of the derangements in bodily economy attending operation have remade surgery again. The improvements that have come about in the last decade or more are not the startling variety that marked the swift progress which came with anesthesia and asepsis. Nevertheless, real improvement in many areas of surgery is readily discernible. The greatest forward strides probably have been made in intrathoracic surgery. Improved techniques in this province of surgery have permitted performance of operative procedures with low mortality rates for conditions which surgeons looked upon with hopeless discouragement and despair a generation ago. Vascular surgery of the thorax is a new chapter in operations being written by the surgeon of today who has schooled himself in the stern discipline of preparing nice dissections of the large blood vessels of the thorax.

The gauge of a surgeon's accomplishment must be measured against the achievement

for that period. It is unfair to compare the performance of a surgeon of one generation with that of another. There were good surgeons 25 years ago but surgical organization in well appointed hospitals is much better today. Anesthesia is considerably better, our understanding of the nutritional requirements of surgical patients is far better and our knowledge of care of patients before, during and after operation is better. Nursing care also is considerably better than it was a generation ago. We know more about shock and replace blood loss more adequately. We have learned that it takes time and patience to do operations well and that maintenance of a steady state of the patient throughout the operative procedure has done away with the necessity for hurry, a circumstance which condemned many an operation to failure although the advocates of the method continued to insist it was the chief determinant in deciding whether a patient would survive.

In other chapters of surgery there has been less conspicuous but nevertheless noticeable improvement. Gastrointestinal surgery has been quite static for a generation. Yet, with similar improvements in technique which gave such accelerated momentum to the surgery of intrathoracic conditions, the last few years also have witnessed the extension of operations upon the gastrointestinal canal to older age groups and substandard risk patients with a constantly declining mortality rate. Apart from the items listed above which played so important a rôle in the flowering of intrathoracic surgery, an additional factor which has been of particular significance for the improvement of results in abdominal surgery has been increasing appreciation of the importance of suction applied to duodenal tubes to obviate the occurrence of intestinal distention following operation. Moreover, prevention of gastric retention precludes regurgitation into the lungs, a former frequent cause of postoperative pneumonia.

The discovery of the sulfonamides and penicillin has lent a great impetus to surgery as it has to medicine as a whole. The discovery of a new fact can change the whole complexion of a problem. But how plodding a process is the discovery of a single new fact!

Fig. 1. Weighing scale employed in the general surgical operating rooms at the University of Minnesota Hospital. Such a scale weighs to an accuracy of 1 gram. The use of dry sponges (saw on exposed viscera such as small bowel or lung) serves to inform the surgeon of the blood loss at any juncture of the operation.

Little wonder that a new fact is a priceless possession and that we immortalize the names of men who have added a single important fact to knowledge. Keener appreciation of previously known facts lends its stimulus to a branch of knowledge the impact of a new fact, however gives impetus and momentum that is felt over a tremendous range a new fact is like a ferment in changing a static state into a dynamic one. It breathes new life into an undertaking

FORTUNES OF SURGERY

There is no equation or formula which can give a complete answer to the important question of what may be expected of an operation

Fig. 3. Use of the Red-cross Litter on platform for patients who can not stand. This scheme of weighing needs the help of nurses and an orderly to lift the patient, with least discomfort to him, onto the litter. (Surg. Gyn. Obst., 94 Feb. 2A)

Fig. 2. Patients undergoing difficult operations on stand on a bedside weighing scale the day following operation. Patients are weighed in the morning before rounds, the gain or loss in weight from the preoperative weight helps to determine the water and sodium chloride requirements for the next 24 hour period.

The planning of the procedure, the nature of the organization in which the surgeon works, his training and his general outlook on his responsibilities, the character of the dissection he performs, the breadth of his comprehension of what constitutes satisfactory preoperative preparation and postoperative care and the vigilance with which the anesthetist, the surgeon and his staff and the nursing staff watch over the patient—these are the determinants of the outcome of an operation. And yet even in this enumeration some things are left to chance. On this latter score, may I say that the surgeon who leaves the care of a number of items to chance is an unsafe surgeon. No matter how well we have standardized the performance of a certain operative procedure, they are not all performed alike. The hemostasis in one operation may not be as satisfactory as we may have wished it or the somewhat irregular placement of a single suture may have angulated an anastomosis whether gastrointestinal or vascular such is

Fig. 4. a. A new bedside weighing scale built for me by Mr. John A. Phelan of the scientific apparatus shop. This scale, with an electrically driven motor to hoist the patient up and let him down permits weighing the patient in bed.

to affect its function unfavorably. The performance of surgery demands a high level of concentration together with a harmonious co-ordination of eye, hand and mind. Perhaps it was this circumstance that Thomas Fuller had in mind when he said the surgeon stands in need of an eagle's eye, a lady's hand and a lion's heart. For the difficult surgery of today a sturdy pair of legs is also an indispensable necessity!

Fatigue undermines the surgeon's efficiency. There is no effective antidote for the fatigue and weariness which beset the surgeon in long and strenuous operative ordeals. Intentness of purpose urges him on to the performance of his best effort, though it cannot drive away the subjective feeling of fatigue and the physical impairment of efficiency which comes with long sustained application under trying circumstances. There are operations being performed now of such magnitude that the surgeon occasionally stands in greater need of postoperative treatment than the patient on completion of the operation! It is my feeling that an impetus may be lent to the safe conduct of patients through some of the more difficult and tedious operations, when university clinics come to attach greater importance

b. The scale in use. The hoisting device lifts the patient a few inches off the bed. There is no interruption of the administration of intravenously administered fluids.

to some of the techniques employed by industry and football coaches in combating the inefficiency of fatigue by sending in a fresh team. No surgeon of experience will deny the deterioration of accomplishment which attends fatigue. The interests of the patient which should be the paramount concern in any operation would be served better by such an expedient.

The great need of more precision techniques. Surgery and surgeons generally stand in serious need of greater precision techniques in the gauging of patients as satisfactory risks for operation. In the assessment of whether the preoperative preparation is adequate in the intricacies of the operation as well as in post-operative management. There is a mortality and morbidity of treatment as well as of disease! Let no surgeon mistake this. We are prone to say the patient died despite all our efforts. How often the converse is true: the patient died because of what was done. Are we so blind or dull that we cannot see this? It is in the critical analysis of the events leading to unhappy outcomes that surgeons have the opportunity to improve themselves and to improve surgery.

We can all point out in our own experiences the repercussive effects of ill advised treatment. In this connection I like to tell under graduate students of an experience in which I was in a manner a participant. My family has a summer home not far from the Twin Cities. One of my neighbors is a veterinarian.

One summer before the long war years, we both had young dogs. My good friend the veterinarian said to me his dog had manifested a few signs of distemper and he was in the process of vaccinating him for it. Being a good neighbor he volunteered to do as much for mine. I decided to let my dog take his chances with the distemper. He did contract it and was ill for a week or so but made a complete and satisfactory recovery. A short time following our initial conversation I asked the veterinarian how his dog was getting on. He said he feared he had overdone the vaccination of his dog and in consequence the dog's appetite was poor. As a stimulus to appetite, he was giving the dog some strychnine and the dog was showing signs of improvement. A week later our paths crossed again and I asked the doctor how the dog was getting along. He said that the dog had been overtreated with strychnine causing him to have convulsions. In an effort to control the convulsions, he had anesthetized the dog with ether and had given him too much ether and had killed him! We too are guilty of occasionally shortening lives when we are striving to make them longer and happier. And often that rôle is not as self-evident as it was in this story.

How many patients lose their lives each year because of mismanagement of the water and electrolyte requirement of patients? To say many is an understatement. Is it happening in your clinic? It has in ours. I believe that when surgeons generally become more alert to the factors of safety in this intricate problem they will have taken an important step forward in improving their own accomplishments. I shall not say very much about our general plan of management of this problem here for I have discussed the problem at length elsewhere (2, 3, 4). I have the feeling however that when surgeons lend a more attentive ear to assessing such needs of patients in a more quantitative manner they will be agreeably surprised to observe what great help such guides afford them.

Routine use of dry sponges in operations affords an opportunity to assess the gain in weight, thus informing the surgeon of the extent of the blood loss at any juncture of the

procedure. To replace fluids in kind and in amount with that lost is obviously the best treatment. And to weigh patients before and immediately after operation as well as in the convalescent period is the best of all guides in helping the surgeon orient himself with reference to the electrolyte and fluid requirements of his patient. Moreover the weighing scale is far more sensitive in the detection of minor changes in body hydration than are changes in hemoglobin. Obviously such routine weighing of patients undergoing major surgery is often unnecessary for the problem of hydration seems to resolve itself by employment of simpler means involving less trouble constituting therefore needless effort. But who counts the cost of labor when lives are at stake? Do we not read almost daily in the newspapers of the heroic sacrifices of men with no view to cost or personal danger, assuming large risks in the effort to save a life? In the hospital in which you work have lives not been lost because the surgeon and his staff were not alert to the changes occurring in hydration and electrolyte balance of the patients? We have lost patients needlessly through this agency while professing an interest in the problem of water and electrolyte requirements of postoperative patients, at the same time, enlisting the helpful co-operation of the best talent that a University Clinic has to offer in the solution of such problems. It is in just such situations that the weighing scale has its chief virtue, in affording a provision of what will happen if abnormal contractions or increases in body weight continue uncorrected. This I may also say since the expedient of weighing patients undergoing major surgery has become routine practice on the writer's surgical service, loss of life through disorientation of the surgical staff with reference to the important problem of hydration of patients has been more than decimated. I must confess we still go astray occasionally but usually recognize the error of our ways before disaster overtakes us. It is in the surgery of elderly substandard risk patients, who tolerate abuses poorly and especially in the surgery of gastrointestinal conditions necessitating the presence of intubated duodenal tubes, that the weighing scale is a

time qua non if the surgeon aspires to do such operations with risks not far out of line with those assumed by younger standard risk patients. Reducing the mortality score as I stated previously consists essentially in the recognition of error and its correction. If a patient's weight in the early postoperative phase can be maintained within 2 to 3 per cent of the preoperative value (plus or minus) the surgeon is assured that the water and electrolyte requirements of his patient are being met satisfactorily. Pneumonia and cardiac failure as a consequence of overhydration owing largely to the administration of too much sodium chloride we saw not infrequently postoperatively among older patients undergoing extensive and complicated surgery before routine employment of the weighing scale. Routine weighing of such patients to detect deviations from the preoperative normal is at least as important as taking the patient's temperature. When surgeons learn to deal satisfactorily with the difficult problem of hydration of postoperative surgical patients, one of the most formidable of hazards to safe conduct of the patient through operation will have been surmounted. It is a surgeon must learn to hurdle.

Mr. Albert Sullivan Jr.¹ in studying the case records of 151 consecutive patients undergoing major surgery upon the gastrointestinal canal, during the first 6 months of 1946 observed that in this group slight losses of weight were far more common than gains of weight. Only 11 patients (7.3 per cent) showed a weight gain of 2.5 per cent or more total body weight, whereas 76.8 per cent exhibited weight losses of 2.5 per cent or more. The greater number of this group lost weight during the first 5 days after operation. Only 1 patient lost more than 6 per cent of the body weight. The average age in this group of patients was 58.9 years. These findings suggest that our surgical staff is more sensitive to weight gains than losses in weight. All of the patients in this group had intubating duodenal tubes, presenting therefore essentially the most difficult problems of maintenance of

water and electrolyte equilibrium. Obviously the cause of the weight loss in most instances was administration of too little sodium chloride accompanied by employment of moderately generous quantities of 10 per cent glucose solution. The effect of such therapy is to promote diuresis a circumstance that is pleasing to surgeons especially when dealing with a group of patients whose mean age is high. Needless to say it is important to take careful note of small deviations from the preoperative weight in order to keep fluctuations in weight at a minimum. Of the total measurable output of body fluid 70 per cent was the remainder being constituted largely by the fluid aspirated by the intubating duodenal tube. The average daily administration of sodium chloride was 6.5 grams in the early convalescence of those patients losing 2.5 per cent or more of their body weight. These observations suggest that the daily administration of 6.5 grams of sodium chloride is probably slightly less than enough for patients with intubating duodenal tubes undergoing major surgery upon the gastrointestinal canal.

Acquaintance with and employment of precision techniques by the surgeon and his staff in the various items that hedge about an operation afford the patient the best promise of a favorable outcome. It is the operation without mishap and a convalescence without complication that spells success. Such a procedure also permits early ambulation and early dismissal from the hospital. The convalescence punctuated by complication is synonymous with increased morbidity as well as mortality. The circumstances which characterize success and failure are often 'minor differences but it is out of infinite and alert attention to detail that success is compounded. By very duty of relentless perseverance in his attack upon the factors that constitute the "minor differences" between success and failure the surgeon can gradually overcome the hazards that are undermining his efforts. Recognition of error when accompanied by a resolute determination shared by the surgeon's staff to avoid the repetition of such mistakes, is the best assurance against failure. It is a source of ever recurring wonder to me how well patients get on after serious operations un

¹Medical student from Tulane, doing a voluntary externship in the surgical wards during the summer of 1946.

attended by complication. And when surgeons succeed in making the unpleasant trials of the waking and recovery periods following operation more agreeable, patients will be less likely to regard an operation as a journey through the valley of the shadow of death.

SUMMARY AND CONCLUSIONS

Order is heaven's first law. It also must rank among the most important of guiding principles in the surgeon's code. Without order the results of operation are unpredictable. A surgeon who has regulated his activity in accord with semblance of good order comes well prepared for operation. Preparation has to do with readiness as well as fitness. He does not undertake operations for which he is not prepared. Nor does he perform unnecessary operations. The surgeon's trust is as sacred as life itself and must not be profaned. The surgeon who has schooled himself in the preparation of nice and precise anatomical dissections does not permit himself to be hurried. He places the safety of his patient above every other consideration. And the security of the patient demands not alone that, the surgeon watch over him with tender and observant care during operation but that the surgeon has seen to it that no detail is overlooked in the preoperative preparation, and that alertness and vigilance characterize the care of the patient after operation.

The success of operations depends upon a harmonious blend of many things. The practical wisdom garnered from experience is in

essence an issue resulting from detection, a knowledge, and correction of error. Though we falter if we are in earnest in our determination not to fail, success is inevitable. We must learn to count the cost less and value the result more. The surgeon's objective should be the elimination of all avoidable causes of death after operation. The safe conduct of the patient through operation is a matter upon which an instruction can be given more readily than consistently followed. Portia's prudent counsel in the Merchant of Venice³ on this score is well known to you. She said, "If to do were as easy as to know what were good to do, chapels had been churches and poor men's cottages princes' palaces. It is a good divine that follows his own instructions. I can easily teach twenty what were good to be done than be one of the twenty to follow mine own teaching. The fortunes of our patients are determined by the manner in which the formalities of surgery are heeded by the surgeon. The functions of surgery and its future growth as a benevolent and helpful aid to man suggest that improvement in accomplishment demands that the surgeon be mindful and observant of the stern disciplines of his handcraft.

CLINICAL USES OF STREPTOMYCIN IN MEDICINE AND SURGERY

H CORWIN HINSHAW M.D. Rochester Minnesota

ALTHOUGH streptomycin was first described by Schatz, Bugie and Waksman less than 3 years ago the drug is already in full commercial production and distribution and has proved to be a useful antibacterial agent in medical and surgical practice. The full possibilities and limitations of streptomycin treatment in several important diseases remain to be determined but progress has been extremely rapid in the last 2 years and should continue at an accelerated rate.

The usefulness of streptomycin is dependent on the fact that this antibiotic agent is effective against several pathogenic bacteria which are not susceptible to the action of other anti-bacterial substances. These bacteria include some frequently encountered gram negative bacilli and above all the bacillus of tuberculosis.

The treatment of infections of the urinary tract due to bacteria sensitive to streptomycin has been extensively studied (7-9) and it is uniformly agreed that streptomycin is of value in such treatment although its potentialities are limited. These bacteria frequently acquire a resistance to the action of streptomycin within a few days hence if permanent results are to be realized, it is extremely important that conditions favorable to persistence or recurrence of infection be corrected promptly if possible. Strains resistant to streptomycin are more likely to be developed if there is obstruction to flow of urine or if calculi or other anatomic defects permitting survival of bacteria are present. The importance of proper timing of treatment in relation to surgical intervention becomes obvious.

Bacteremia due to gram negative bacilli sometimes occurs, especially in association with severe infections of the urinary tract and

as a postoperative complication following operation on the infected urinary tract. Streptomycin therapy frequently is effective in treatment of such bacteremia (7-9) when due to organisms sensitive to this antibiotic agent (9).

Meningitis due to sensitive micro-organisms especially gram negative bacilli should be treated with streptomycin utilizing both parenteral and intrathecal routes of administration. My associates and others (7-9, 10) have reported favorable results in influenzal meningitis treated with streptomycin.

Since acute peritonitis is frequently of such serious portent and due to such an admixture of pathogenic micro-organisms I would recommend the simultaneous use of all available antibacterial agents in medical treatment. The combination of streptomycin with penicillin appears to be thoroughly logical under these circumstances, especially if the peritoneal cavity is soiled with intestinal contents.

Wound infections due to mixed bacterial flora should frequently be treated with both penicillin and streptomycin especially if bacteriologic examination proves the presence of sensitive micro-organisms. Fully adequate débridement should first be carried out to minimize the possibility of a recurrence of the infection due to bacteria which have acquired a resistance to the action of streptomycin.

Streptomycin is of real value in some cases of chronic suppurative pulmonary disease such as bronchiectasis (11) and especially as a preoperative measure preparatory to pulmonary resection. Here again it should usually be used in conjunction with penicillin and administered as an aerosol. The duration of treatment will vary from 1 to 2 weeks or more the treatment being continued until sputum is reduced in amount, changed in character and rendered bacteriologically sterile or nearly so. Cases of bronchiectasis suitable for streptomycin therapy may be selected by merely ex-

aming smears of the sputum stained by Gram's method. If numerous gram-negative bacilli are present, streptomycin is likely to be a useful adjuvant to penicillin therapy.

Acute and chronic infections of the respiratory tract due to organisms of the *Hemophilus* and *Klebsiella* groups may be treated successfully with streptomycin (7, 9).

The treatment of tularemia with streptomycin has yielded spectacular and promptly curative results (5). Streptomycin may be considered a specific remedy for tularemia; hence the accurate diagnosis of tularemia becomes of greatly increased importance.

Brucellosis and typhoid fever are caused by organisms which are only moderately sensitive to streptomycin. The latest available reports of streptomycin therapy in these diseases are not encouraging (9) except possibly during the most acute phases with demonstrable bacteremia.

When streptomycin is administered orally it is not absorbed from the alimentary tract in significant amounts; hence its oral administration is useless for treatment of systemic infections. However, the antibiotic agent is not destroyed but remains within the lumen of the bowel to exert its antibacterial effect on the intestinal flora (6). The possibilities of orally administered streptomycin have not been fully studied for preoperative preparation of patients prior to intestinal operation either as a substitute for sulfonamides or in combination with sulfonamides. My surgical colleagues have made sufficient use of streptomycin in this manner to indicate that it does have practical possibilities.

The action of streptomycin on cultures of *Mycobacterium tuberculosis* was noted early (13) but this is a property which had been described previously for a number of other substances of microbial origin (4) and many synthetic chemical compounds (14). When streptomycin proved to be extremely effective against experimental tuberculosis of guinea pigs (2, 3) its clinical possibilities were recognized and quickly explored.

The greatest potentialities for streptomycin therapy appear to exist in treatment of tuberculosis (8) including some surgical types of tuberculous infection. This is due to the fact

that no other practical and effective antibacterial therapy is available against the bacilli of tuberculosis and to the fact that this bacillus is much more sensitive to streptomycin than are the other common pathogenic bacteria. Furthermore, the tubercle bacillus remains sensitive to streptomycin for at least a few months before becoming drug resistant (15) and this permits realization of satisfactory therapeutic effects, especially in lesions of recent origin. It also has been found that some rather poor candidates for radical surgical treatment of pulmonary tuberculosis may be rendered excellent candidates after a few months of treatment with streptomycin. Likewise postoperative tuberculous complications may be amenable to streptomycin therapy or may be prevented by use of the drug.

Many types of tuberculous infection ultimately produce destructive changes which no drug can directly benefit. Antibacterial therapy is only suppressive in this and other diseases and will yield permanent benefit only if natural mechanisms of healing can achieve supremacy during the limited period of a few months during which the bacilli are sensitive to the action of streptomycin. Selection of tuberculous patients for streptomycin treatment must be undertaken with the greatest care. During the past 2 years my colleagues and I have followed a few simple rules, based on our concept of the action of streptomycin. These rules may be enumerated as follows: (1) Patients who are making satisfactory progress on conventional forms of treatment for pulmonary tuberculosis or who are likely to do so should not receive streptomycin. (2) Patients who have terminal types of pulmonary tuberculosis, especially when bilateral destructive changes are present, and who could not become candidates for surgical treatment are not regarded as good subjects for streptomycin treatment. (3) Patients who have old chronic nonprogressive fibrocavous and cavernous types of pulmonary tuberculosis are not likely to experience satisfactory results and hence should not be treated. (4) Priority is treatment has been given to more acute, progressive pulmonary tuberculosis of recent origin. In general, patients with most severe constitutional symptoms and with least destructive

pulmonary changes have obtained the best results from streptomycin treatment. These are individuals with naturally low resistance or with depleted resistance, and hence those most in need of assistance from antibacterial therapy. It should be repeated that such treatment should be given before the disease has wrought changes in the lung such as cannot be repaired within a few months. All patients with pulmonary tuberculosis chosen for streptomycin treatment should have a component of exudative disease and the larger the proportion of exudative to proliferative tuberculosis the better.

The clinical results of treatment of such patients often are realized promptly. Within the first few weeks fever declines, cough and expectoration decrease, appetite and a sense of well being return and the patient begins to regain lost weight. Later, after 6 to 8 weeks of treatment, roentgenographic evidences of improvement of exudative lesions are first noted. Usually within 3 to 5 months maximal clinical and roentgenographic improvement has been attained. This would appear to be the time for surgical treatment of remaining disease and especially for closure of any remaining cavities, such as might serve as sources for subsequent bronchogenic dissemination of the disease.

Ulcerating tuberculous lesions of the larynx, the hypopharynx and the tracheobronchial tree have healed rapidly and so far without exception in our small series of 10 cases. These patients have received combined treatment with intramuscularly administered streptomycin and streptomycin aerosol.

Some types of extrapulmonary tuberculosis have responded to streptomycin treatment with remarkable uniformity. This is especially true of chronic long standing draining sinus tracts, which usually close within a few weeks, but these will remain closed only if treatment is continued for several weeks after apparent healing. In renal tuberculosis and tuberculous cystitis temporary and palliative effects have been observed frequently but actual healing of small lesions has been observed rarely possibly because the kidney lacks the power to heal tuberculosis readily. In only a few cases of tuberculosis of bones and joints has strepto-

mycin been used but results have been encouraging. Much remains to be learned about streptomycin in relation to orthopedic surgery in the treatment of tuberculosis of the skeletal system.

Until the advent of streptomycin there was no way in which the course of tuberculous meningitis and miliary tuberculosis could be modified. Even with streptomycin treatment there is an extremely high mortality rate. However in most cases of early tuberculous meningitis the patients respond promptly to adequate intramuscular and intrathecal streptomycin treatment but all too frequently these gains are not permanently sustained. At least temporary clinical remission is almost the rule following streptomycin treatment of early but acute and severe tuberculous meningitis. Consciousness is regained often within a few days, fever declines within a few weeks, a sense of well being returns and frequently patients appear to be essentially normal, even for several months. Subsequent exacerbations of the disease are likely to recur and not to respond to treatment. However this may not always be true for in 3 cases of proved tuberculous meningitis arrest of the disease continued for several months following discontinuation of a 6-month course of intensive treatment. One patient has no residual neurologic signs, one is normal except for deafness and the third has apparently received severe damage to the central nervous system, especially the cerebellum. Although nearly a year has passed since the onset of illness in these 3 cases it is too early to classify the patients as cured. Five patients who had tuberculous meningitis have died despite treatment but 3 of these did not receive what is now regarded as adequate treatment and the remaining two were first seen at a late stage of the disease.

Disseminated hematogenous tuberculosis of miliary type has not responded previously to any form of treatment and spontaneous recoveries have been extremely rare. With streptomycin treatment it is possible to bring about a complete clinical and roentgenographic remission in a large proportion of cases but unfortunately the recurrence rate has been very high thus far and three of our four treated patients have eventually died. The remaining

patient has remained well for 6 months but cannot yet be classified as cured.

Tuberculosis of the alimentary tract and tuberculous peritonitis have not been studied adequately but symptomatic improvement of the 5 patients who have been treated at the Mayo Clinic has been striking.

Although clinical effectiveness of streptomycin is readily demonstrated in many types of tuberculous infection the results are often not permanent and frequently do not compare with results achieved in acute diseases treated with other antibacterial agents such as penicillin. The limitations of streptomycin treatment in tuberculosis must be emphasized constantly in this day of miracle drugs and the emphasis must still be placed on the known effective methods of treating tuberculosis, especially care in a sanatorium and collapse therapy. The place of streptomycin in tuberculosis therapy has not been determined but this agent is much more likely to supplement than to supplant the proved effective standard methods of treatment.

Streptomycin usually is administered by intramuscular injection doses being given every 3 to 4 hours and totaling from 1 to 3 grams per day. The lower limits of effective dosage have not been fully explored nor can final statements be made concerning the upper limits of safe dosage. Streptomycin is more toxic than penicillin but very little difficulty is experienced in treatment of more acute diseases which require only a week or two of treatment. When treatment is continued beyond 2 to 4 weeks nearly all patients will experience some disturbance of equilibrium (1) occasionally to a severe degree. Fortunately compensation is achieved in all or nearly all instances more promptly in younger than in older patients and no permanent disability is likely to result. Sluggish response to caloric stimulation of the vestibular apparatus is usually noted for many months and perhaps permanently even when there is no residual functional disability. The cause and significance of these changes have not been determined fully and are in need of complete investigation. Deafness has been noted occasionally but hearing is ordinarily regained if treatment is discontinued promptly. In this respect, strep-

tomyacin resembles such drugs as quinine and salicylates. Evidence of renal limitation has been noted occasionally but serious renal damage is not nearly so likely to occur as is true with administration of sulfadiazine. Streptomycin should be used with caution when there is reason to fear pre-existing impaired renal function because the drug may not be readily excreted under these conditions.

SUMMARY

Streptomycin is an effective antibacterial remedy of value in treatment of several infectious diseases not amenable to treatment with other antibacterial substances.

Streptomycin may be used in combination with penicillin for treatment of mixed infections such as are likely to occur in the presence of acute peritonitis, chronic suppurative pulmonary disease and contaminated wounds.

Streptomycin has value in treatment of infections due to gram-negative bacteria occurring in the blood stream, in the meninges, or in the urinary tract.

Streptomycin is highly specific in treatment of tularemia. It has but little value in treatment of brucellosis and typhoid fever.

Streptomycin is the only practical antibacterial substance which is useful in treatment of tuberculosis. Limitations of streptomycin therapy in this disease appear to be imposed by the destructive and granulomatous changes produced in tuberculous tissue and by the fact that the drug cannot be depended on to destroy tubercle bacilli in the human body.

THIOURACIL AND IODINE

The Preoperative Management of the Thyrotoxic Patient

BENJAMIN GOLDMAN B.Sc., M.D. F.A.C.S., JAMES D WEAVER, M.D. and
E. M. RALSTON A.B. M.S. Ph.D. M.D., Erie, Pennsylvania

FROM the reported experiences in the collected literature, 3 salient characteristics of thiouracil therapy have been emphasized. These have been the prompt clinical response to the drug, the standardization of the dosage at 0.6 gram, daily by which the basal metabolic rate is reduced 1 per cent each day and most important, that thiouracil toxicity has appeared in about 14 per cent of all patients so treated. Since so much value yet so much danger has been found in the treatment of the thyrotoxic patient with thiouracil, some safer method of management should be sought to obtain the maximal therapeutic effect of the drug with the greatest margin of safety. This has been the objective of the present study in admittedly small series since from a total experience of 527 thyroidectomies only 20 recent hospital cases were considered suitable for this form of therapy.

There were 16 females and 4 males varying in age from 23 to 76 years. The average age of 45.1 years was equivalent to that of 190 thiouracil treated patients reported by Lahey. In the series were 9 nodular and 9 diffuse goiters and 1 recurrent goiter in each group. The tissue submitted from the recurrent diffuse goiter was reported by the pathologist as adenocarcinoma. All admission basal met

abolic tests were made after at least one day of rest in bed. The highest was plus 72.4 per cent and the lowest plus 25.1 per cent. The average plus 43.57 per cent. This approximated Lahey's average of plus 49 per cent. Admission leucocyte counts ranged from 10,050 to 41,500 with an average of 71,355. All other clinical laboratory determinations and radiological examinations were performed routinely on admission but have been omitted from this report. Medication was withheld until the laboratory findings were charted. Bed rest except for 2 hours daily was the rule. In addition ice caps were applied to the head and precordium intravenous fluids were administered as indicated and sedation obtained by the generous use of phenobarbital. The average daily dose of phenobarbital was 4 grains. This included the larger doses of 3 grains to 9 grains given the night before operation. While the Bartlett's have advocated larger amounts to produce narcosis and semi-anesthesia these patients were easily managed on the smaller dosages since avertin was used as a basal anesthetic 45 minutes before the scheduled operating time. All patients received 0.6 gram of thiouracil daily divided into 3 doses each of 0.2 gram. The longest period of administration was 21 days the shortest 6 days and the average 11.9 days. There were 4 exceptions to this dosage. In 3 patients it was necessary to increase the amount and in 1 to decrease it. In Case 8 patient previously iodine resistant, required 0.6 gram daily for 8 days 0.8

From the Hamot Hospital, Erie, Pennsylvania—Dr. Goldman, Attending Surgeon, Dr. Weaver, Resident Physician, Dr. Ralston, Assistant Surgeon.
Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

62 days Thyroidectomy was performed without incident and without postoperative storm in all cases. In Case 5 a large nodular intrathoracic goiter in a patient aged 65, the admission basal rate was plus 31.3 per cent and grave myocardial damage without heart failure was present. The rate was reduced to plus 14.2 per cent by thiouracil and patient was then iodinated. Death occurred less than 30 minutes after the incision was made as the right lobe and isthmus were removed. This was a cardiac death in the thyrocardiac group which is known to carry the highest mortality rate.

Since end results and the time spent in a hospital have always been pertinent factors in this form of management should be compared with present methods of combined ambulatory and hospital care. Thiouracil was used an average of 11.9 days plus Lugol's solution 6.2 days or a total preoperative time of 18.1 days. Case 5, the operative death and Case 20 in which patient refused operation have been deducted from these figures. The average postoperative time was 6.8 days or during all of this time each patient was under medical control while receiving a known toxic drug. This control cannot be exercised over out patients having at their personal disposal 1 or 2 weeks supply of thiouracil. Until thyroid disease can be cured medically, the thyrotoxic patient must eventually come to operation. While the standard 0.6 gram daily dose of thiouracil effectively reduced the basal metabolic rate this small series of 527 thyroidectomies and the thousands re-

ported elsewhere have clearly pointed out that Lugol's solution, bed rest and sedation as well as thiouracil are still factors essential to the successful management of the thyrotoxic patient.

SUMMARY AND CONCLUSIONS

1 Thiouracil has a field of usefulness and should be limited to the preoperative preparation of the thyrotoxic patient.

2 The dangers which have been previously reported appear to be due to the prolonged use of a potent drug.

3 These dangers can be minimized in the hospital by careful observation, study and the individualizing of treatment to the needs of each patient.

4. It would seem unwise to place in the hands of an out patient a dangerous drug and allow such a patient to be removed from regular and controlled observation.

5 The use of iodine in conjunction with thiouracil is a sound and safe practice since it eliminates uncontrollable operative hemorrhage and thus ensures safe hemostasis.

6 Reduction of the basal metabolic rate to limits between plus 15 per cent and plus 30 per cent by thiouracil followed by the administration of large doses of iodine reduces the preoperative preparation time to the economic advantage of the patient without materially increasing the surgical risk.

TABLE II.—CLASSIFICATION OF CLINICAL DISORDERS OF FLUID AND ELECTROLYTE BALANCE*

Water disequilibrium	Salt disequilibrium
1. Acute water deficit.	1. Extracellular salt water deficit.
2. Chronic water deficit.	2. Extracellular salt water deficit with water deficit.
3. Absolute water excess.	3. Extracellular salt water deficit with relative water excess.
	4. Extracellular salt water excess.
	5. Extracellular salt water excess with relative water deficit.
	6. Extracellular salt water distributional shifts.
	7. Any of above (1, 2, 3, 4, 5, 6) with changes in base-bicarbonate (alkalosis or acidosis)

*Intracellular salt disequilibrium states are not considered in constructing this table.

gresses at a rate rapid enough to prevent the kidney from excreting salt in sufficient amounts to maintain the solute concentration of the body fluids at a normal level. This state is accompanied by intense thirst if the individual is conscious. The clinical signs that accompany acute water deficit are oliguria, dryness of mucous membranes, elevation of body temperature (rectal), and hallucinations, disorientation, mania, and coma in order of progression of the deficit. The laboratory signs are a high urine specific gravity (if renal function is good), high blood urea, and concentration of red blood cells, plasma proteins, chloride and sodium in the blood.¹ The correlatives necessary for making the diagnosis are the physical signs of water deficit, a high urine specific gravity and the absence of signs of an extracellular salt water volume deficit (see extracellular salt water volume deficit).

Chronic water deficit. (Primary water deficit with a normal solute concentration of body fluids, Fig. 2.) Chronic water deficit is the most frequently encountered disturbance of fluid equilibrium in psychiatric institutions. It differs from acute water deficit because a compensatory renal excretion of salts (Na and

Fig. 2. At left, normal extracellular fluid; at right, chronic water deficit.

K) occurs as the body content of water falls (4). This tends to maintain the solute concentration of body fluids within normal limits. However, salt concentrations finally rise when the deficit of water becomes so great that in sufficient water is provided to the kidney to excrete the salt necessary to keep solute concentrations normal.

In the treatment of chronic water deficit one must remember that salt deficit is associated with the water deficit even though no obvious loss of salt by vomiting, diarrhea, or sweating has occurred.

The cause of chronic water deficit is a decrease in the rate of water accretion of such a degree that the rate of total water gain is less than the rate of minimal water loss. However, the discrepancy between the gain and the loss of water is not so great as to prevent the kidney from holding the solute concentrations of body fluids within the ranges compatible with health.

The most frequent cause of the disorder is a reduction in the sensorium that under conditions of health keeps the water content of the body within a relatively narrow range of variation. Its frequency of occurrence is high in psychopathic states, organic brain disease (senile alcoholic, luetic, postapoplectic), drug addiction, chronic febrile illnesses, geographic limitation of water intake, and chronic painful states (peripheral vascular disease, causalgia, chronic infection, arthritis and neoplasia).

The clinical signs of chronic water deficit are predominantly those of an extracellular salt water (base) deficit provided that the development of the deficit proceeds slowly enough for the kidney to keep the solute concentration of the body fluids constant. However the signs of acute water deficit may be added to those of extracellular salt water defi-

¹It is especially that diminished elasticity of the skin, softening of the eyeballs, and longitudinal wrinkling of the tongue are not listed as signs of acute water deficit.

MOYER FLUID AND ELECTROLYTE BALANCE

erally associated with states of water deficit or excess, or states of alkalosis or acidosis. A continued excretion of sodium in excess of that taken into the body is its cause. The excretion may be extrarenal (vomiting, diarrhea, fistulae) or renal. The renal excretion may be compensatory as in chronic water deficit or pathologic as in renal tubular hypofunction (hydro-nephrotic atrophy). The associated presence of water equilibrium disturbances will depend upon the concomitant rate of water accretion. If less water is drunk during the development of the extracellular salt water deficit than was lost through kidney, skin and lung, an associated deficit will be present. The development of changes in composition alkalosis or acidosis, are mainly dependent upon the composition of the fluid lost from the body. Polyuric obstruction with vomiting of an acid solution tends to be associated with an alkalosis. Loss of pancreatic juice, an alkaline solution (pancreatic fistula), produces acidosis.

The signs and symptoms of an extracellular salt water deficit are variable. They depend in part upon the rate of formation of the deficit, upon the water content of the body other than that in the extracellular fluid, upon the concomitant rate of potassium loss, and upon the degree of the "uncompensated" compositional changes that may be associated with the deficit. The signs and symptoms of a relatively uncomplicated deficit are as follows:

- 1 Usually there are no definite signs or symptoms associated with a salt water deficit of 0 to 2 per cent B in a healthy adult.³ However, in the aged in winter and in the chronically ill, a reduction of the extracellular salt water volume of this degree may be attended by severe symptoms and signs.

- 2 An extracellular salt water volume decrease of 2 to 4 per cent B is accompanied by apathy, weakness, somnolence, anorexia, brief periods of nausea, reduced affective responses,⁴ transient vertigo on assuming the erect posture, a soft pulse with insignificant

and variable changes in systolic blood pressure and pulse rate, and a slightly sticky skin. This stage has been called the "early barbituric acid-depressive phase of salt deficiency."

- 3 An extracellular salt water volume decrease of 4 to 6 per cent B ($1/3$ to $1/2$ of the extracellular fluid volume) is associated with an increase in severity of the above signs and symptoms and in addition occasional unproductive retching, syncope on attempting to stand, a lowered blood pressure—frequently to "shock" levels, a variable pulse rate—usually tachycardia, a subnormal temperature if ambient temperature is below 85°F,⁵ a wrinkled tongue, sticky skin, "putty" muscles, and soft eyeballs.

- 4 Coma finally supervenes and death occurs with reductions of the extracellular salt water volume of $1/3$ to $1/2$ of the "normal."

The laboratory signs are variable and are in part dependent upon the amount of the deficit (little change of solute concentration with small deficits regardless of rate of water ingestion) (1) upon the composition of the salt solution excreted (plasma chloride falls faster if stomach contents are lost than if small bowel contents are) upon the rate of water accretion in deficits of salt water volume greater than 2 to 3 per cent B (see chronic water deficit and extracellular salt water deficit with "relative" water excess) and upon the rate of development of the deficit.

The finding of "normal" blood solute or red blood cell concentrations does not rule out the presence of an extracellular salt deficit. However, a diminution of the solute concentration (Na and Cl) with an increase in the concentration of red blood cells (high hematocrit) is positive evidence that a relatively severe and rapidly developed extracellular salt water deficit exists. The relationship of the changes in the solute and red blood cell concentrations to the salt water deficit are qualitative but usually not quantitative. Therefore the history and the physical examination constitute the best bases for ascertainment of the existence of salt water deficit.

B₀—original body weight.

³When extracellular salt water volume deficits are associated with a proportionately greater water deficit, when they are very great and the individual is near death, when it occurs in infancy or when it is incurred in hot climates, an elevated temperature is usually found.

⁴The more rapidly the deficit develops, the more severe are the symptoms and signs that accompany a given deficit.

⁵Author's observations on C. L. M. Three trials, fasting state for 14 hours, volume deficit induced by continuous duodenal drainage for 50 hours excepting for eight $1/4$ -hour periods with the tube clamped to permit the drinking of water to allay severe thirst.

⁶No desire to smoke, read the paper or talk to anyone.

Theoretically the actual water content of the body in this state, although it is usually in deficit, may actually be in excess of the individual's usual content in health even though extracellular fluid volume is below normal in spite of its dilution with water. To have this particular condition readily obtain it is necessary that the loss of extracellular sodium proceed without much reduction of intracellular base and with a rate of water accretion that is faster than its rate of loss.

A full blown picture of an extracellular salt water deficit with water intoxication does not occur often with environmental temperatures below 85 degrees F. However at low environmental temperatures it may complicate the course of recovery from trauma (operative, 20 thermal 22, crush) provided that too much water is given too soon or that too little sodium is given too late. The rate of excretion of positive loads of water by the kidney is reduced and may approach zero with severe salt water deficits. In oliguric or anuric states associated with an extracellular salt water deficit, the restoration of the solute volume and the concentration of the extracellular fluids by the administration of an appropriate interstitial salt solution is of primary importance in the re-establishment of kidney function. If an attempt be made to force urine flow by the administration of water before the extracellular fluid volume deficit is corrected, severe water intoxication may be induced, and an oliguria converted to anuria.

Extracellular salt water deficit with water excess (miner's cramps) occurs fairly frequently in hot environments if a sodium deficit is incurred while the drinking or the administration of water is not limited (21). Heavy work by an untrained, unacclimatized person (high rate of Na loss through sweating) and a reduction of sodium intake below minimal rate of loss in a person at rest (alcoholism, febrile illnesses, etc.) are the usual immediate causes of the sodium deficit.

through fistulous tracts (duodenal, choledochal, pancreatic and external) with the chronic loss of extracellular fluid from granulating wounds; and with inattention to details in the care of people with large wounds (placing individuals with large open wounds or granulating surfaces in tube of water rather than saline, the covering of large wounds with wet dressings that are wet with water or hypotonic salt solutions as boric acid).

The physical signs and symptoms of an extracellular salt water deficit with relative water excess are those of an extracellular salt water deficit, those of an absolute water excess, and those of uncompensated compositional changes if they are present. Obviously large individual variations in signs and symptoms will be present. The laboratory signs of an extracellular salt water deficit with relative water excess are as follows: a low sum of the plasma chloride and bicarbonate (below 115 to 120 mEq per liter) in the absence of acetoneuria, a low urine chloride concentration and a normal or an increased concentration of red blood cells. These are the most essential correlates to be considered in formulating a diagnosis of an extracellular salt water deficit with relative water excess.

Extracellular salt water excess (Fig. 7) The symptoms and signs of a rapidly induced relatively small excess are listed in Table III. The sensible loads at the end of the period of loading varied from 2.8 to 4.1 percent of body weight because of the excretion of the salt water (renal and intestinal) that occurred during the loading period. The volume of

Fig. 7. At left, normal extracellular fluid; at right, extracellular salt water excess.

fluid given always amounted to 5 per cent body weight in 5 hours.

The signs and symptoms vary and seem to be partially dependent upon the composition and tonicity of the solution that was administered, especially by the oral route. Haldane and Priestley described this relationship earlier. The salt solution drunk "was meant to approximate to the salt content of human serum and was found to be much more palatable than 6 p.c. sodium chloride solution—a point of some practical importance because it

TABLE III.—SYMPTOMS AND SIGNS OF EXTRACELLULAR SALT WATER EXCESS IN MAN

Group 1. Nine healthy fasting men, loaded with 5 per cent B_u of 85 per cent NaCl solution at rate of per cent B_u per hour by mouth.

Group 2. Five healthy fasting men, loaded with 5 per cent B_u of 0.85 per cent intravenous salt solution (NaCl, 14 mEq. per liter plus NaHCO₃, 30 mEq. per liter in water) at rate of per cent B_u per hour by mouth.

Group 3. Five healthy fasting men, loaded intravenously with per cent B_u of 0.85 per cent NaCl solution at rate of per cent B_u per hour (0.85% N Cl is 5% glucose solution produced more severe post-administrational muscular incoordination).

Group 4. Five healthy fasting men, loaded with 5 per cent B_u of 0.6 per cent NaCl solution at rate of per cent B_u per hour by mouth.

was found to be almost impossible to drink rapidly two or three litres of sodium chloride solution without producing vomiting' (17)

Hoarseness and a sensation of 'heavy eyelids' are the only constant symptoms associated with a sensible load of 2.8 to 4.1 per cent body weight of the above solutions. Greater positive loads of salt solutions are associated with the gross collection of fluid in subcutaneous tissue, in body cavities and in some organs. Therefore gross overloads of 15 to 25 per cent body weight are associated with variable signs and symptoms that have an intimate relationship to the degree and rate of impairment of breathing, circulation and renal function

Extracellular salt water excess rarely exists without a disturbance in the content of water in the body in relation to total solutes. A relative water deficit is commonly associated with it. This state is described below

Extracellular salt water excess with relative water deficit (Fig. 8) This syndrome may be readily induced during the postoperative period and after trauma by the exclusive use of an isotonic salt solution to provide for the water and salt needs of a person who cannot

Fig. 8. At left, normal extracellular fluid; at right, extracellular salt water excess with water deficit.

eat or drink. It is physiologically analogous to the illness induced by drinking sea water to satisfy thirst.

If 0.9 per cent sodium chloride solution (159 mEq. sodium per liter) is the only fluid infused into healthy fasting men the urine excreted during the first 24 hours does not contain much more sodium than the infusate per unit volume. Consequently the amount of water made available to the body from the saline solution is smaller than the insensible loss of water and the concentration of salt in body fluids increases.

If the intravenous injection of 0.9 per cent sodium chloride in water or 0.9 per cent sodium chloride in 5 per cent glucose into a healthy man is continued at a constant rate during the next 24 hours so that an amount of solution roughly in excess of 3 per cent of body weight is administered in 24 hours, a new equilibrium state tends to be established. This state is characterized by the excretion of the salt given that day and by a concentration of sodium chloride in the urine sufficiently greater than its concentration in the infusate so that enough water is thereby provided to balance the insensible loss, and the concentration of salt in the body remains at the level reached

the previous day or it decreases. If the above solutions are given as the sole source of water during renal insufficiency states or during the immediate postoperative period when the kidneys' ability to excrete sodium in high concentrations in the urine is limited, a much greater excess of sodium chloride and a greater deficit of water in relation to total body solutes will exist before the new equilibrium state is reached. Indirect evidence indicates that under certain circumstances the relative water deficit may reach such proportions as to be associated with anuria in the presence of edema. The syndrome of "acute salt intolerance" is now thought to be due to salt excess with a relative water deficit.

The symptoms and signs are as follows: disorientation, anorexia, nausea, vomiting, a diminishing rate of urinary flow in relation to the amount of fluid retained, hoarseness, and the collection of fluid subcutaneously, in the lungs, and in body cavities. The plasma sodium concentration tends to be elevated, and the red blood cell count and plasma protein concentration tend to be reduced. If oliguria is present, the nonprotein nitrogen of blood increases.

Changes in composition of extracellular fluid (Departure from the normal electrolytic pattern of extracellular salt water.) Changes in the composition of extracellular fluid can be of many types. A few of them are hypoproteinemia, hyperproteinemia, hypocalcemia, hypercalcemia, hyponatremia, hypernatremia, and acidosis alkalosis. Only two of them, acidosis and alkalosis of nonrespiratory origin, will be considered.

The degree of acidosis or alkalosis present should be looked upon as a measure of the organism's inability to compensate for a change in the relationship of the bicarbonate ion to the anions of stronger acids (SO_4 , HPO_4 , Cl , lactate) in the extracellular salt water. In other words the actual change in the hydron concentration (acidosis or alkalosis) is a measure of the ineffectiveness of the respiration, the renal function, and the buffer systems to compensate for an alteration in the relationship of acid (H_2CO_3) to base bicarbonate (BHCO_3)—HA/BA. This change in relation ship in the type of acidosis or alkalosis con-

sidered here is due to a shift in the proportion of HCO_3 to the sum of the other anions of stronger acids than H_2CO_3 in the extracellular fluid (Cl , HPO_4 , SO_4 , lactic and other organic acids).

The signs and symptoms of a relatively un complicated¹ base-bicarbonate deficit ("acidosis") and of a base-bicarbonate excess ("alkalosis") are relatively mild. The reduction by one-half² of the base bicarbonate (to 10–14 mEq per liter) by drinking hydrochloric acid is attended by moderate dyspnea and hyperpnea with mild exercise, such as walking at one's usual rate on level ground and severe dyspnea after rapidly climbing three flights of stairs similar to that which may be experienced during the last 50 yards of the "440". There is no appreciable dyspnea or sense of fatigue at rest, but recovery of a feeling of well being after exercise is long delayed with the above base-bicarbonate deficit. No great change in the mental reactivity was noted at the above level of base bicarbonate deficit. Greater noncompensatory deficits of base bicarbonate to one-quarter of normal (7–8 mEq per liter) in adults (13) and to less than one-fifth of normal (4–5 mEq per liter) in children (13) may not be attended by any grossly detectable signs or symptoms indicating an impairment of the function of the central nervous system.

Similarly the elevation of base bicarbonate to 40 to 52 milliequivalents per liter of plasma (CO_2 combining capacity 90 to 120 volumes per cent) may not be associated with any detectable mental or physical signs of illness, even the tendency to the development of muscular cramps and hyperexcitability of tendon reflexes may not be apparent. Hypopnea is difficult of detection without actual measurement of the minute volume of respiration. Therefore it appears that most of the symptoms usually ascribed to "acidosis" (base-bicarbonate deficit)³ and "alkalosis" (base-bicarbonate excess) are the result of the concomit-

¹ Acidosis—rapidly induced by drinking N/100 hydrochloric acid.

² Alkalosis—rapidly induced by drinking .33 per cent NaHCO_3 in water.

³ Disorientation, anorexia, nausea, vomiting, weakness, spathic pain in muscles, paralytic ileus, hypotension, fast pulse.

ant disturbances in physiologic components other than base bicarbonate. Fagge in 1874 (9) first called attention to the apparent rôle played by dehydration (salt water deficit) in the clinical picture of diabetic coma and to the partial efficacy of the injection of a saline solution into the blood. However following Stadelmann's implication of acid poisoning as the cause of diabetic coma, the rôle of the salt water volume deficit in the picture of diabetic coma was largely forgotten for a time.

Within the last two decades Fagge's original ideas have been rediscovered, and it is now realized that salt water deficits (extracellular

($\text{Na}^+ \text{Cl}^- \text{HCO}_3^-$) and intracellular ($\text{K}^+ \text{HPO}_4^{--}$)) may quite frequently accompany nonrespiratory base bicarbonate deficits and base bicarbonate excesses. Consequently as more experience is gained in treating individuals suffering from disturbances in body fluid equilibrium, it is realized that the symptoms and signs of severe alkalosis or acidosis, with their ubiquitous physiologic effects, may be minimal and that it should be more generally realized that the direction of one's efforts toward their correction without taking cognizance of the relatively large neutral salt water deficits that are associated with them will occasionally result in inadequate salt water replacement. Then the signs and symptoms ordinarily ascribed to the alkalosis or acidosis, excepting those related to respiration and in the case of alkalosis those relating to ionized calcium deficit, may persist though to a lesser degree after the carbon dioxide combining capacity has been returned to normal. Therefore, in the treatment of a base-bicarbonate excess or deficit the replacement of the attendant neutral salt water deficit should always be kept in mind. See Table IV for the treatment of acidosis and alkalosis.

Extracellular salt water distributional shifts (Fig. 9) (Reciprocal variations in the extracellular salt water volume of various tissues, with the total extracellular salt water volume of the body remaining constant.) This type of disturbance in fluid equilibrium is frequently seen by the surgeon. Varying degrees thereof universally accompany all trauma. The experiments of Underhill Kapsinow and Flske

Fig. 9. Extracellular distributional shift from torso to lower extremities.

(23) demonstrated that the rate of shift of fluid into an injured area is rapid and that after the fluid has entered the injured area, it does not leave it in appreciable amounts for 50 to 70 hours. The increment of fluid in the injured area actually constitutes a functional loss of salt water and plasma proteins from the body (the uninjured part). Red blood cells also collect in the injured tissue largely because of the capillary dilatation and the static flow of blood in it. This constitutes a functional hemorrhage although the total red cell volume remains within normal limits as determined indirectly from the hematocrit and plasma volume determinations or directly using carbon monoxide.

A distributional shift of body fluids following trauma is similar to an uncomplicated extracellular salt water deficit or a chronic water deficit. Clinically significant distributional shifts of body fluids are associated with trauma (mechanical, e.g. crushing injuries, fractures of the pelvis and femora; major operative procedures; thermal, e.g. scald and burn; and chemical, e.g. peritonitis following perforation of the duodenum or gall bladder) with thrombophlebitis with infections such as gas gangrene, typhus fever and trichinosis and with toxic dermatoses. This list is not complete.

Salt water (see Table IV distributional shift) blood and plasma protein constitute the basic therapeutic elements in the treatment of distributional shifts of body fluids.

More detailed and specific directions for the treatment of disturbances in the equilibrium of body fluids than those included in this paper can be found in the *Journal of the American Medical Association* (3) and in the *New England Journal of Medicine* (1).

MOYER FLUID AND ELECTROLYTE BALANCE

TABLE IV—TREATMENT OUTLINE

Fluid volume state	Repair solution	Concentration of solute in repair solution	Composition of repair solutions		
			Compositional change in extracellular fluid		
			Alkali normal	Alkali deficit (Minimal—moderate)	Alkali excess (Minimal—moderate)
Acute water deficit	Glucose in water	5, 10, or 15%	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 0.66 4	Sodium chloride	Sodium chloride
Chronic water deficit	Sodium salts	100 mEq/liter*	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 1.0 66	Sodium chloride	Sodium chloride
Extracellular salt water deficit with water deficit	Sodium salts	150 to 300 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 1.0 66	Sodium chloride	Sodium chloride
Water excess	Sodium salts	160 to 320 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 1.0 66	Sodium chloride	Sodium chloride
Extracellular salt water deficit with relative wet excess	Sodium salts	160 to 320 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 1.0 66	Sodium chloride	Sodium chloride
Extracellular salt water distributional shifts	Sodium salts	160 to 320 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 1.0 66	Sodium chloride	Sodium chloride
Extracellular salt water excess with or without relative water deficit	Glucose in water	5, 10, or 15%	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride Ratio $\text{NaCl} : \text{NaHCO}_3 : \text{KCl}$ mEq 1.0 1.0 66	Sodium chloride	Sodium chloride

*Salt dissolved in water or in 5 per cent glucose solution.

When disturbed osmotic pressure occurs with any compositional disturbance, the initial treatment should be directed toward the correction of the osmotic pressure. In the treatment of alkalosis, 1M/100 HCl or a 0.9 per cent solution of NH_4Cl are effective. In the treatment of severe acidosis, sodium bicarbonate (1.5% solution) or sodium lactate (1M/6 solution) may be used. When the signs of shock or liver damage are present, extracellular salt water deficit may not be split by the liver of a person who is very ill and if it is not split, it is not effective in the treatment of acidosis. The amount of sodium bicarbonate needed to correct gives base-bicarbonate deficit or excess may be determined as follows: (1) In the treatment of acidosis, use 60 mEq. per liter of plasma. This 0.66 per cent NaCl solution (66 per cent) per kilogram of body weight can also be obtained by calculation by the use of Van Slyke's nomogram. (2) For the initial treatment of alkalosis, employ the following rule: Take 0.66 cubic centimeters of concentrated HCl (36 per cent) per kilogram of body weight for each mEq. of base bicarbonate in excess above 300 cubic centimeters of sodium; then give it slowly and stop the injection if dyspnea appears. (3) For the initial treatment of alkalosis, employ the following rule: Take 0.66 cubic centimeters of sodium bicarbonate (1.5 per cent) per kilogram of body weight for each mEq. of base bicarbonate in excess above 300 cubic centimeters of sodium; then give it slowly and stop the injection if dyspnea appears. (4) The employment of this formula to calculate the base bicarbonate deficit or excess may be determined as follows: (5) For the initial treatment of alkalosis, employ the following rule: Take 0.66 cubic centimeters of sodium bicarbonate (1.5 per cent) per kilogram of body weight for each mEq. of base bicarbonate in excess above 300 cubic centimeters of sodium; then give it slowly and stop the injection if dyspnea appears. (6) For the initial treatment of alkalosis, employ the following rule: Take 0.66 cubic centimeters of sodium bicarbonate (1.5 per cent) per kilogram of body weight for each mEq. of base bicarbonate in excess above 300 cubic centimeters of sodium; then give it slowly and stop the injection if dyspnea appears.

If the necessary laboratory data are not available, changes in physical signs may be used in regulating the amount of sodium bicarbonate or hydrochloric acid to be given. In the case of severe acidosis, sodium bicarbonate solution (1.5 per cent) may be infused intravenously until the hypervolemia and the dyspnea are relieved. Usually in an adult two liters of 1.5 per cent NaHCO_3 will be enough. With severe alkalosis, 1M/100 HCl or 0.9 per cent NH_4Cl may be given until the carpopedal abnormality, the extracellular salt water deficit that remains is corrected with appropriate volume. After the initial correction with the carpopedal abnormality, the extracellular salt water deficit that remains is corrected with appropriate volume. The extracellular salt water deficit associated with acidosis or alkalosis (correcting alkalosis due to the ingestion of alkali) is almost always relatively greater than the alkali excess or deficit, and therefore after the initial correction of the compositional changes, more salt solution of a relatively neutral reaction should be given to correct the extracellular salt water deficit that remains.

Therapy The conduct of parenteral fluid therapy should be primarily determined from an evaluation of the history, the symptoms, the physical signs, and laboratory data. Laboratory data are valuable but should not be used as the primary determinants of diagnosis or procedure. Some of the reasons for the above statement follow:

a. The quantitative correlation of the departure from normal values of the hemoglobin and the hematocrit with changes in the extracellular salt water volume in experimental sodium deficiency states is poor and is negative occasionally. This is the more especially true the more slowly the salt water deficit is contracted and the longer it exists (14, 15). If hematocrit and hemoglobin changes are used

as bases for the calculation of the fluid need, an underestimation of plasma proteins is also a "poor" constant. In many instances of known sodium salt deficit, the total circulating protein diminishes at approximately the same rate as the volumes of the plasma and the extravascular extracellular fluid do (8). Consequently, the plasma protein concentration may not be above normal even though a dangerous degree of extracellular salt water depletion may be present.

c. The plasma chloride level does not constitute a valid basis for ascertaining either the presence or the degree of change in the extracellular salt water volume. The plasma chloride concentration may not fall and may ac-

tually increase as an extracellular salt water volume deficit occurs as a result of pancreatic or biliary drainage, and it may be below normal when the extracellular fluid volume is normal (hypochloremia secondary to a primary carbon dioxide excess as in emphysema, asthma, depression of breathing by opiates) or when the extracellular salt water volume is even greater than normal (hypochloremia secondary to an excess of water as in water intoxication).

The weight of the body from day to day is not an universally sound physiologic basis for the determination of the salt and water needs of the individual. Distributional shifts of extracellular salt water into the subcutaneous tissues or into serous cavities occasionally occur rapidly and as a result thereof the rest of the body suffers from the depletion of its extracellular salt water—there is need for salt water even though the individual's weight has not changed. Conversely an individual who has been given salt water or plasma in the treatment of injury (burns) usually begins to lose weight rapidly between the fourth and seventh days as the edema of the burned area subsides. Salt water should not then be given to the patient even though he is losing weight because he is excreting the salt that was given to him while the edema was forming and now that the edema is subsiding the salt constitutes an excess. If one assumes that except for the above types of illnesses, weight change is a sound basis for controlling fluid administration he assumes that the ideal water and salt contents of the body are constant. This is likely not true though only a small amount of exploratory research work has been done on the possible changes in the "ideal" body content of water and salt associated with various ills. Under certain circumstances the "ideal" water and salt contents of the body may be larger and under others smaller than they are in the healthy individual.

When determinations of the volumes of plasma and extracellular salt water can be made easily and repeatedly they may become valuable aids in the diagnosis and treatment of disturbances in body fluid equilibrium.

"Ideal" contents may be defined as those most conducive to the rapid recovery of health.

Changes in the concentration of plasma solutes and red blood cells are most valuable as checks of the appropriateness of the diagnosis and treatment.

Because there are no simple dependable means of detecting small extracellular salt water deficits, the daily parenteral administration of salt to those who cannot eat or drink is presumably an expedient that should be employed even though no salt is being lost through extrarenal channels or sequestered in diverse regions of the body. How much salt should be given under these circumstances?

Because healthy nonfasting men habitually eat 2 to 10 grams of salt daily it has been felt that a sick man who cannot eat should receive parenterally at least 5 grams a day in order to maintain his salt balance." However men suffer no apparent harm if their salt intakes are reduced to 1 gram daily. The Tlascalan Indians forgot the taste and the use of salt after they had been cut off from salt for centuries (16). Infants sustain their most rapid period of growth on about a gram of sodium chloride per diem.

It appears likely that the salt that man ingests daily is dictated by taste and habit rather than by actual need, and that healthy men in general have within their bodies more salt than is actually necessary for the maintenance of health. Quantitative salt excretion studies lend support to this idea. The question of the optimal salt intake, during a fast, is still unanswered. From a surgical standpoint, the routine parenteral administration of 5 to 9 grams of salt daily when there is no abnormal functional loss thereof is in certain instances capable of delaying recovery. In fact, a slight deficit of extracellular salt water may be preferable to any excess (even 5 to 9 grams daily) especially during the immediate postoperative period. This belief is supported by a number of reasons:

1. For 2 to 4 days after any injury injected salt solutions tend to collect most rapidly and to a relatively greater extent in the area of injury (19). This phenomenon is very easily demonstrated in anyone upon whom a colostomy has been performed. If no saline is given the transudation from the surface of the loop will be relatively small and it swells

MOYER FLUID AND ELECTROLYTE BALANCE

relatively little, if then 2,000 cubic centimeters of 0.9 per cent saline solution are administered, the transudation and swelling increase rapidly. An enteric anastomosis behaves in the same way, the edema that occurs about the region of the anastomosis is greater if saline is given. Therefore, the resumption of the functional continuity of the intestine following an enterocolostomy or enterocolostomy will tend to be longer delayed as the amount of salt injected is increased. On one occasion an edematous occlusion of a gastrojejunostomy stoma was found to be the cause of a complete gastrojejunal obstruction 24 days after a subtotal gastric resection. The mass of salt given daily was 4 grams over that lost as gastric drainage. No subcutaneous edema was present. Following the second operation, although no corrective operative procedure was carried out, the functional patency of the anastomosis was established after 4 days of zero intake of salt. The rate of healing of wounds tends to be related inversely to the local edema; the greater the edema, the slower is the rate of healing. This is most clearly demonstrated in the experiments performed by Glen, Gilbert and Drinker.

2 The incidence of postoperative pulmonary complications after upper abdominal operations is higher especially in the aged when maintenance doses (5 to 9 grams daily) are infused than when no salt is given unless specific signs of need appear (Unpublished data.)

3 A deficit of extracellular salt water is more easily corrected than an excess.

The adoption of the policy of withholding salt during the immediate postoperative period until signs of its need appear shifts the responsibility for the maintenance of a physiologically adequate extracellular salt water volume from the kidneys of the patient to his physician. This responsibility is big. If signs of illness are present or appear after an operation or injury that are attributable to a functional extracellular salt water deficit contracted by an external loss or an internal shift thereof vigorous saline therapy must be instituted and the consequences of local edema forgotten.

If there are indications for the parenteral administration of fluids, what solution or solutions should be employed? In general the

solution used should be so composed as to effect the return to normal of the various deformations of the body's fluids without producing other deformations that may be more difficult of accommodation by the organism than the original ones were. Obviously, if the kidneys of all sick individuals would perform as do those of healthy men the manufacture of a universally applicable repair solution would be feasible, in fact 0.9 per cent sodium chloride in water or in 5 per cent glucose (glucose-saline) could serve in that capacity.

If a water deficit existed, it could be corrected by the administration of 0.9 per cent sodium chloride in amounts in excess of 3,000 cubic centimeters daily, should the kidney excrete urine that contained 1.8 per cent salt, for then all the salt injected could be excreted in one-half the volume of water that was injected as 0.9 per cent salt, thus making available to the body a volume of water equal to the volume of urine.

If a water excess existed and the kidney excreted the sodium chloride in 0.9 per cent concentration or lower the water content of the body would decrease by an amount equal to, or greater than the insensible loss of water.

If alkalosis existed, the excess of chloride relative to sodium in the 0.9 per cent sodium chloride solution, compared to the concentration of chloride relative to sodium in plasma would serve to reduce the alkalosis (the concentration of alkali) even should the kidneys put out no urine. If acidosis was present, the administration of 0.9 per cent sodium chloride would permit its correction if the kidneys were capable of excreting sufficiently greater amounts of chloride than sodium.

However, the kidneys of men and women who have been injured or operated upon are relatively unable to excrete a urine having a higher concentration of sodium chloride in it than is present in 0.9 per cent sodium chloride, and consequently water deficits tend to be increased rather than alleviated by the administration of 0.9 per cent sodium chloride solution. In addition, the kidney's ability to excrete chloride in excess of sodium is reduced following trauma or an operation, and therefore the correction of an acidosis with sodium chloride may be impossible.

In other words, solutions of 0.9 per cent sodium chloride in water or in 5 per cent glucose (glucose-saline) are not universally applicable repair solutions because the renal function tends to be depressed following operations and trauma. Therefore, the solutions employed in the correction of fluid disequilibrium states should be so constituted as to effect the correction without depending upon the kidneys.

The solutions that fit the physiologic requirement for the correction of the fluid disequilibrium states described herein are listed in Table IV.

The volume of fluid administered and the rate of administration depend largely upon the response of the individual and the constitutional severity of the depletion.¹ Usually the volume of salt solution given in 24 hours should not exceed 6 per cent of the weight of the body unless the rate of functional loss of extracellular salt water continues at a rapid rate, either as a result of the continuance of distributional shifts (burns, trauma, peritonitis, gas gangrene) or as a result of continued high rates of external loss (ileostomy colostomy or other fistulous drainage). Under these latter conditions the infusion of salt water may have to be continued to 10 to 15 per cent of the weight of the body per 24 hours. When a rapid rate of infusion is employed or a large volume of fluid is given repeated auscultation of the chest and gross determination of venous pressure should be performed. If rales appear or if the veins of the neck become distended and tense the infusion should be temporarily discontinued.

After the correction of deficits has been effected, the amount of salt water given daily will depend upon the continued existence of the cause of the deficit. If the cause of the deficit is a distributional shift due to an injury the movement of extracellular fluid into the injured part will tend to decrease rapidly so that after 36 hours there will be little further shift. After 72 to 100 (93) hours have elapsed after the injury the extracellular fluid in the injured part will begin moving back

into the rest of the body and no more salt should be given because a functional excess of extracellular salt water then exists. If the loss of extracellular salt water continues (because of hyposthenemic nephropathy fistulous drainage, diarrhea, vomiting, gastroduodenal drainage) the loss of salt should be made up, as it occurs, by the injection of a saline solution that has the salt compositional pattern of the body fluid lost.² (See Gamble for the composition of various body fluids.) If no salt is lost after the correction of the deficit, very little if any need be given.

Another general physiologic principle that should be kept in mind when one prescribes parenteral fluids is. A primary change in the body's content of one substance is associated with changes in the organism's content of other substances consequently the restitution to normal of the primary change in content does not insure the restitution to normal of the secondary changes upon which the ultimate recovery of the person may rest. For example a man who excretes large amounts of hydrochloric acid into his stomach, develops pyloric obstruction and vomits a large amount of chloride and a smaller amount of sodium are lost in the vomitus. This increases the concentration of base-bicarbonate in the body and the pH of the extracellular fluid increases respiration slows and the amount of carbon dioxide in the body increases, base-bicarbonate is excreted through the kidney and the body's content of base and consequently of extracellular salt water are thereby diminished. Sodium enters the cells of the body (6) and potassium leaves them to be excreted. A deficit of potassium is incurred thereby. The volumes of plasma and of extravascular extracellular salt water decrease plasma protein leaves the blood stream (8) and the total circulating protein falls although none is lost externally. The red cell mass actually declines although the hematocrit may rise (14).

Now let the extracellular salt water volume deficit be replaced by the infusion of 0.9 per

¹Men with extracellular salt water depletion associated with signs of "shock" receive more solution at a faster rate than those having extracellular salt water depletion without signs of "shock."

²Gastric gives NaCl 45 to 66 per cent, gastric drainage with free hydrochloric acid in it, gives NaCl 45 to 66 per cent; hyposthenemic nephropathy and enterostomy drainage (ileostomy or long-tube section) gives NaCl plus NaHCO₃ plus KCl (see Table IV); pancreatic fistula, give osmotically equivalent means of NaCl plus NaHCO₃ (5 grams NaCl plus 4 grams NaHCO₃ per liter).

MOYER FLUID AND ELECTROLYTE BALANCE

cent sodium chloride solution the chloride and sodium deficits and a part of the carbon dioxide and base-bicarbonate excesses are relieved. There still exists a deficit of plasma protein, a deficit of red blood cells, and an intracellular potassium deficit and sodium excess. (The chemical signs of an intracellular potassium deficit are a persistently high carbon dioxide combining capacity, a high blood urea (or non protein nitrogen), and a low chloride concentration in plasma [4].) If an attempt is made to "correct" the high carbon dioxide combining power and the "hypochlor emia" by further administration of sodium chloride, the deficit of potassium tends to be aggravated regardless of whether the sodium chloride is retained or excreted and the chloride concentration of plasma remains low and the carbon dioxide combining power high.

Therefore, it is obvious that the infusion of sodium salts alone will not satisfy the physiologic demands of the organism after reconstitution of the extracellular salt water volume and that the transfusion of whole blood and the administration of potassium salts should be considered as integral parts of the treatment of a large salt water deficit (7) especially if it has developed slowly and is associated with pronounced physical signs such as great weakness, atonic muscles and hypotension. Upon theoretical (10) and clinical grounds the transfusion of blood should be withheld until partial reconstitution of the extracellular volume has been effected in order to minimize the tendency for the intravascular agglutination of red blood cells and clotting. Darrow (4 to 7) has demonstrated recently that a deficit of potassium frequently accompanies disturbances of extracellular fluid equilibrium and that it has great physiologic and clinical significance.

SUMMARY

A clinical plan is presented for the recognition of disturbances in the equilibrium of body fluids.

The disturbances in equilibrium considered are (1) acute water deficit (2) chronic water deficit (3) absolute water excess (4) extracellular salt water deficit, uncomplicated (5) extracellular salt water deficit with water defi-

cit (6) extracellular salt water deficit with water excess (7) extracellular salt water excess with water deficit (8) extracellular salt water excess with water deficit, (9) changes in composition of extracellular fluids (electrolytic pattern) (10) distributional shifts of extracellular salt water.

The general principles of therapy involved are

- 1 It is better to treat the man than it is to treat his "blood chemistry," plasma proteins hematocrit, or weight. A presumptive clinical understanding of the types of disturbances in the equilibrium of body fluids may be gained from a correlation of the history and the physical examination of the patient. The laboratory data are valuable as checks of the diagnosis and treatment, but they should not be used as primary bases for either
- 2 Sodium salts should be given when they are needed and should be withheld when they are not.

- 3 A primary change in one physiologic variable, such as the sodium content of the body is attended by secondary changes in other physiologic variables, consequently, the reconstitution of the primary variable to "normal" content does not insure the return to normal of the secondary variables upon which ultimate recovery may rest. Decreases in the volume of circulating red blood cells and plasma proteins and in the mass of intracellular potassium are important secondary variables associated with sodium deficiency, especially if the sodium deficit has developed slowly.

- 4 The kidneys of patients treated by the surgeon are often not "alert" enough to alter a 0.9 per cent solution of sodium chloride to fit the need of the organism; therefore, appropriately balanced salt solutions should be used.

USE OF BLOOD AND BLOOD SUBSTITUTES

JOHN D STEWART A B M D Buffalo New York

IN recent years much new information regarding the nature origin and function of different elements of the blood has become available through the researches of biochemists physicists physiologists and clinicians. In many instances the clinical applicability of such information has been obvious and the patient has derived immediate benefit. In this field as elsewhere in medicine progress in the care of the sick depends not only on the fundamental contributions from laboratories of basic science but on the clinician's alert and intelligent appraisal of new facts and on his skillful application of these new facts in the clinic.

Whipple and his collaborators have done much to define the facts of protein metabolism and the conditions governing the regeneration of the plasma proteins and hemoglobin (10 14 15). The quality and quantity of protein ingested the state of the liver the presence or absence of infection or intoxications the factor of individual organismal variation and the availability of iron to the body have been shown to be critical conditions in the maintenance of normal hemoglobin and plasma protein concentrations and blood volume. They have shown that the healthy animal for example can replace all its circulating plasma protein in 3 days under the stimulus of plasma withdrawal while taking a protein rich diet. Hemoglobin which contributes six times as much protein to the blood as does plasma protein takes about six times as long for replacement. Body protein accretion (both new hemoglobin and tissue protein) is believed to go through the transition stage of plasma protein. The protein of the plasma thus constitutes a pool which is drawn upon by the cells throughout the body and which is in constant interchange with cell protein. The studies of

Schoenheimer and others using tagged elements supports the conception of continual and rapid movement of amino acids through out the proteins of the body. The blood then must be regarded as a tissue which is in dynamic equilibrium with the other tissues of the body and its composition and volume are maintained relatively constant only through a set of remarkably complex and continuous reactions.

Of particular interest to surgeons also is the work of Cohn and his group in the fractionation and characterization of the plasma proteins (3 4 9). As methods have been developed for the separation of the different proteins of the plasma it has become possible to prepare them for tests of their function with a consequent better understanding of the physiological rôle of the individual proteins. The properties of the different fractions are of great clinical import, and must be considered in the intelligent use of blood and blood substitutes. For example the colloid osmotic force of plasma protein is essential to the maintenance of the volume of the circulating blood and when the plasma protein concentration falls below a so-called critical level in the neighborhood of 5 grams per 100 cubic centimeters reduction in blood volume and dangerous tissue edema may occur. It must be remembered however that the albumin fraction is much more important than the globulin fraction in this respect, for although the albumin molecule comprises only about 60 per cent of the plasma protein it is a much smaller molecule than globulin and provides about 80 per cent of the colloid osmotic pressure of the plasma. It has been shown that the antibody properties of the plasma reside in the globulin component and reduction in this fraction by malnutrition prolonged abnormal loss or impairment of the body's power to form globulin lowers resistance to infection (2). The clotting power of the blood depends particularly on two components of the plasma protein namely, fibrin

USE OF BLOOD AND BLOOD SUBSTITUTES

JOHN D STEWART A B M D Buffalo New York

IN recent years much new information regarding the nature origin and function of different elements of the blood has become available through the researches of biochemists, physicists physiologists and clinicians. In many instances the clinical applicability of such information has been obvious and the patient has derived immediate benefit. In this field as elsewhere in medicine progress in the care of the sick depends not only on the fundamental contributions from laboratories of basic science but on the clinician's alert and intelligent appraisal of new facts and on his skilful application of these new facts in the clinic.

Whipple and his collaborators have done much to define the facts of protein metabolism and the conditions governing the regeneration of the plasma proteins and hemoglobin (10 14 15). The quality and quantity of protein ingested the state of the liver the presence or absence of infection or intoxications the factor of individual organismal variation and the availability of iron to the body have been shown to be critical conditions in the maintenance of normal hemoglobin and plasma protein concentrations and blood volume. They have shown that the healthy animal for example can replace all its circulating plasma protein in 3 days under the stimulus of plasma withdrawal while taking a protein rich diet. Hemoglobin which contributes six times as much protein to the blood as does plasma protein takes about six times as long for replacement. Body protein accretion (both new hemoglobin and tissue protein) is believed to go through the transition stage of plasma protein. The protein of the plasma thus constitutes a pool which is drawn upon by the cells throughout the body and which is in constant interchange with cell protein. The studies of

Schoenheimer and others using tagged elements supports the conception of continual and rapid movement of amino acids through out the proteins of the body. The blood then must be regarded as a tissue which is in dynamic equilibrium with the other tissues of the body and its composition and volume are maintained relatively constant only through a set of remarkably complex and continuous reactions.

Of particular interest to surgeons also is the work of Cohn and his group in the fractionation and characterization of the plasma proteins (3 4, 9). As methods have been developed for the separation of the different proteins of the plasma it has become possible to prepare them for tests of their function with a consequent better understanding of the physiological rôle of the individual proteins. The properties of the different fractions are of great clinical import and must be considered in the intelligent use of blood and blood substitutes. For example the colloid osmotic force of plasma protein is essential to the maintenance of the volume of the circulating blood and when the plasma protein concentration falls below a so-called critical level in the neighborhood of 5 grams per 100 cubic centimeters reduction in blood volume and dangerous tissue edema may occur. It must be remembered, however that the albumin fraction is much more important than the globulin fraction in this respect, for although the albumin molecule comprises only about 60 per cent of the plasma protein it is a much smaller molecule than globulin and provides about 80 per cent of the colloid osmotic pressure of the plasma. It has been shown that the antibody properties of the plasma reside in the globulin component and reduction in this fraction by malnutrition prolonged abnormal loss or impairment of the body's power to form globulin lowers resistance to infection (2). The clotting power of the blood depends particularly on two components of the plasma protein, namely fibrin

ogen and the globulin prothrombin. In addition, an antihemophilic globulin has been isolated and this element, missing in hemophilia, can be supplied from normal plasma to control the bleeding of hemophilia. Largely through the work of Cohn and his group under the stimulus of war time needs, these various derivatives of the plasma proteins have been put to practical test for the benefit of the sick and the wounded.

These remarks serve as a reminder that in the use of blood and blood substitutes in surgical practice one is dealing with fundamental physiological considerations. The better the understanding of the need of the patient, the clearer the objectives and the less empirical the practice, the better the result.

The rest of this discussion will be concerned with two common surgical problems, namely hemorrhage and secondary shock. These conditions will be considered in relation to therapy by the intravenous administration of whole blood, plasma, albumin solution and protein hydrolysates. By the latter term is meant the mixture of polypeptides and amino acids formed by the enzymatic breakdown of a high quality protein such as casein or lactalbumin. Such hydrolysates in 5 or 10 per cent solution are nonallergenic and nonpyrogenic when properly prepared. They may be regarded as a blood substitute in that they provide the essential amino acids for the construction of plasma protein and hemoglobin when given intravenously.

Hemorrhage. In the healthy adult the volume of the blood comprises about 8 per cent of body weight, but variations of from 6 to 10 per cent have been found in different individuals (8-18). The blood volume tends to remain constant in the same individual and is probably more closely related to surface area and height than to weight. The healthy person can withstand a sudden loss of one third the blood or even more (up to 1.5 or 2 liters) but this is not true of many of the patients the surgeon must treat. Malnutrition, previous hemorrhage, infection, trauma, disease of cardiovascular system, liver or kidneys, reduce the power of the organism to make the life-saving adjustments required in overcoming critical blood loss.

As previously noted the blood volume is not to be regarded as a fixed entity as if contained in a rigid walled vessel. Not only may the size of the vascular bed vary rapidly through vasodilatation or vasoconstriction and ischemic shunts, but the blood is in diffusion equilibrium with the larger reservoirs of interstitial and intracellular fluid. With loss of blood an immediate inflow of fluid from outside the capillary bed begins, a process which is detectable by fall in red cell count and hematocrit. Furthermore in hemorrhage protein is mobilized from parenchymatous organs such as the liver and red cells are drawn into circulation from the spleen and bone marrow. The more rapid the loss of blood, the less the time for successful compensation and the lower the physiological reserve of the patient the smaller his capacity to endure hemorrhage. It has been shown by studies of hemorrhagic shock in animals that the longer hemorrhagic hypotension and tissue anoxia are allowed to go uncorrected the less the likelihood of survival. After a certain point damage to such organs as the liver and brain becomes progressive. The urgent need for correction of blood loss is thus emphasized. Ideally the loss of blood should be made good as it takes place.

A great service has been done practicing surgeons by Coller and his co-workers, as well as others, in providing evidence that the amount of blood lost during common operations in good hands may be large (1.5-6.7-12.20). Many surgeons unquestionably had failed to appreciate that operative and post-operative shock commonly stemmed from uncorrected hemorrhage. Further proof is convincingly available in the major teaching clinics of the country today where by the free use of blood transfusion during and after operation surgical procedures of hitherto impossible magnitude are being successfully performed (13). As Coller has pointed out, (a) the amount of bleeding at operation is almost always greater than the surgeon suspects, (b) there is no practicable method of measuring the extent to which bleeding has occurred at any given time during operation and (c) replacement is most effective when whole blood is given as the loss occurs (5). Every

STEWART USE OF BLOOD AND BLOOD SUBSTITUTES

surgeon undertaking major surgical procedure should familiarize himself with the range of values for blood loss at various operations and ideally he should measure the losses at his own hands in a series of cases.

The replacement therapy for massive hemorrhage seems obvious though from time to time the obvious has been held suspect. Whole blood has been lost in the operative field into body cavities into tissue planes or to the surface and whole blood should be given in treatment (11-19). The blood must be carefully matched it must be given in large enough quantity it must be given without delay. The acutely depleted blood volume lowered cardiac output and tissue anoxia urgently require relief. In acute hemorrhage plasma or albumin injected intravenously will increase blood volume but further dilution of hemoglobin and crippling of the mechanism for oxygen-carriage results. Under these circumstances the systolic blood pressure may temporarily rise and produce a false sense of security while the patient's condition is actually worse.

Following a severe nonfatal hemorrhage unless the loss has been completely corrected by blood transfusion a period ensues during which anemia, hypoproteinemia and reduced blood volume are common findings. Unless the patient is receiving large amounts of iron the anemia is apt to be of the hypochromic microcytic type and the hypoproteinemia may be associated with a relatively greater reduction of albumin than of globulin. During the convalescence from severe hemorrhage further blood transfusions are still frequently in order but protein requirements may be advantageously contributed to by infusions of plasma and albumin. A better source however of amino acids is protein hydrolysate in 5 or 10 per cent solution.

Secondary shock. In the state of secondary shock as distinct from neurogenic transitory hypotension there are present reduction in cardiac output and blood flow fall in blood pressure and usually evidence of peripheral arteriolar constriction. As a rule there is lowered basal metabolic rate and body temperature rapid pulse shallow respiration and sweating. Secondary shock may be seen in

medical as well as surgical conditions and the syndrome may be classified on an etiological basis as follows:

- 1 Loss of propulsive force, or cardiogenic shock as seen in coronary occlusion and severe cardiac arrhythmias.

- 2 Dilatation of the vascular bed as seen in overwhelming invasive infections or in transection of the spinal cord.

- 3 Mechanical interference with blood flow as in volvulus of the intestine cardiac tamponade tension pneumothorax pulmonary embolism or mesenteric thrombosis.

- 4 Primary reduction in blood volume as in wound shock hemorrhage, burns war gas poisoning and severe dehydration.

The classification of secondary shock in this manner is of value in that it emphasizes the varied nature of forces which may produce the same clinical picture though in many cases more than one of these major causes may be at work. It follows that treatment will vary likewise.

It is probably a fair assumption that reduction in cardiac output is present in secondary shock due to any of the above causes and that lowered blood volume is present in most instances. However, blood transfusion may be dangerous rather than beneficial in cardiogenic shock or pulmonary embolism and though blood transfusion is helpful in intestinal strangulation it is equally important to correct the mechanical defect by early surgical operation. In the state of secondary shock due to fulminating infections restoration of blood volume by infusions of plasma and by blood transfusions is in order but of greater urgency perhaps is treatment of the infection itself as by surgical operation antibiotics and sulfonamides depending on the case (17). The uncritical use of blood transfusion in secondary shock without analysis of its cause is therefore to be condemned.

In the state of secondary shock due to losses from the circulation or in other words in primary oligemic shock, successful treatment must be based on knowledge of the nature of the losses. In wound shock, including the shock incident to surgical operation oligemia is due to loss of whole blood and the treatment that is needed is blood transfusion in suf-

ficient volume. Furthermore the treatment of such cases of hemorrhagic oligemia does not end with recovery from the hypotension as was pointed out above. Incomplete restoration of lost blood, the presence of complicating infection, the wasting effect of the reaction of injury raise the need for protein. The intravenous route must often be employed in meeting this need, and 5 or 10 per cent amino acids solutions, plasma, albumin and whole blood must be given.

To illustrate the need for discrimination further, the parenteral fluid requirements in wound shock and in burn shock may be compared. In both conditions there is severe reduction in the volume of circulating blood. In wound shock however whole blood has been lost, and the hematocrit and red cell count are normal or low, the plasma protein concentration is normal or low. In burn shock, plasma has been lost in large amounts and albumin frequently to a greater extent than globulin, the hematocrit and red cell count are sharply elevated. Correction of blood composition here is important as well as restoration of blood volume and the immediate intravenous therapy of choice is infusion of plasma or albumin solution. In both wound shock and burn shock blood and protein hydrolysates and to a less extent plasma and albumin solution may be required intravenously in later convalescence.

CONCLUSIONS

In conclusion certain general principles involved in the use of blood and blood substitutes in the treatment of hemorrhage and shock are listed.

1. Careful matching of blood before transfusion is essential in minimizing reactions and renal damage; plasma for infusion should be of the pooled mixed variety, or it should be typed.

2. Deficiency of hemoglobin and deficiency of plasma protein often occur together, whether the lack is acute or chronic.

3. In the restoration of depleted blood volume by intravenous injections normal blood

corposition as well as normal volume should be the aim.

4. Acute losses of hemoglobin are less easily repaired by the body than are losses of plasma protein.

5. In infections, toxic states and trauma regeneration of hemoglobin and plasma protein may be greatly impaired.

6. The longer tissue anoxia due to hemorrhage and shock is allowed to go uncorrected the less the likelihood that the patient will recover.

7. In hemorrhage and shock as seen in surgical patients the need for blood transfusion and for infusions of protein and the protein derivatives often continues during convalescence.

LIGATION OF THE INFERIOR VENA CAVA IN THROMBOSIS OF THE DEEP VEINS OF THE LOWER EXTREMITIES

J ROSS VEAL, MD, FACS HUGH HUDSON HUSSEY MD, F.A.C.P. and
EARL BARNES MD Washington District of Columbia

LIGATION of the major veins to limit propagation of blood clots and prevent pulmonary embolism has become a standard procedure. The point of ligation of the involved vein depends upon the level of the blood clot and the extent of distention of the vein. The only safe rule to follow is to ligate above the clot through a normal segment of vein just below a main tributary. The majority of cases of thrombosis of the veins of the lower extremity can be detected while the clot is still below the inguinal ligament. In these, ligation of the femoral vein for the deep venous thrombosis, and the same phenous vein for superficial thrombosis usually terminates the process. However in some the disease has extended to such a level that ligation of the inferior vena cava becomes necessary. Ligation of the inferior vena cava is not a new procedure. It has been quite widely used in pelvic thrombophlebitis. However it has only recently been used to any extent in the treatment of thrombosis of the deep veins of the lower extremities. We have performed ligation of the inferior vena cava in 30 cases of ascending thrombosis of the deep veins of the lower extremities. A report of these cases forms the basis for this communication.

INDICATIONS FOR LIGATION OF INFERIOR VENA CAVA

Although the indications for ligation of the inferior vena cava were essentially the same in all of our cases, the basic venous pathology was quite varied (Chart 1). In this series there were 3 types of venous thrombosis, namely phlebothrombosis, acute femorotibial thrombophlebitis, and thrombophlebitis in varicose

veins (Table I). The relative dangers of pulmonary embolism in the various types and the necessity for ligation of the inferior vena cava in the cases we are reporting can best be shown by description of the pathology and clinical course of each type.

PHLEBOTHROMBOSIS

Phlebothrombosis usually begins in the small veins of the legs or feet. The clot is attached at first only at its origin. Propagation is the characteristic quality of this type of venous thrombosis. As the original mass of clot begins to organize the vein wall at this level becomes thickened edematous, and inflamed. As new clot is added it extends steadily upward floating freely in the blood stream. The clot gradually fills the involved veins and eventually becomes organized and fixed to the vein wall. This process may require many weeks. Until there is complete organization and fixation of the thrombus it may be dislodged at any time and produce pulmonary embolism. Phlebothrombosis is particularly dangerous because at first there may be no local symptoms. Its existence often becomes known only after the patient has suffered one or more episodes of pulmonary embolism. As the clot extends upward more venous channels become occluded and local signs and symptoms develop. In all of the cases in this series there were local signs and symptoms of venous thrombosis. The common signs are edema of the foot, ankle, and leg, dilated superficial veins, cyanosis of the nail beds, and often a fall in local temperature. Pain in the calf is the most important symptom. This may be constant but is more often noted on motion of the foot or leg or on pressure over the veins. Fever is frequently absent and when present is quite mild. Leucocytosis is usually absent. Phlebothrombosis of the deep veins of the legs accounted for 25 of the cases in this series.

pathetic blocks were performed over a 3 day period before there was relief of symptoms. The deep veins became thrombosed and superficial collaterals developed rapidly.

The remaining 4 unilateral cases all developed thrombosis of the deep veins of the normal side with massive edema of that limb. The process was gradual and at no time was there any disturbance of the arterial circulation. In all of our 30 cases there has been some degree of postoperative edema of both legs. This has been controlled by properly fitted elastic stockings. We have used a series of leg exercises in order to expand the collateral circulation gradually (Chart 3). The legs are elevated on 4 soft pillows immediately after operation. Walking motion exercises of the feet and legs are given frequently. As the edema subsides or if negligible throughout the pillows are gradually lowered. About 10 days following operation the patients are allowed to dangle legs over the side of the bed—still using the exercises. About 14 days after the operation the patients are allowed to walk. Elastic stockings are then fitted and are worn at all times except while in bed. The patient gradually resumes free activity. All of the patients that survived have been rehabilitated to the point of resuming full time occupations. There has been no ulceration of the legs. There is a marked difference in the rapidity of development of collaterals in the males and females. In the males the superficial collaterals have predominated and in the females the deep collaterals, and often there is no dilatation of the superficial veins.

VENOUS COLLATERAL PATHWAYS FOLLOWING LIGATION OF THE INFERIOR VENA CAVA

When the inferior vena cava is ligated many collateral pathways develop. Some of these carry blood back to the inferior vena cava above the point of ligation; others communicate with the portal vein or the superior vena cava system. Among the most important deep collateral routes is the communication of the hypogastric vein with the inferior mesenteric vein through the hemorrhoidal plexus. Another major route is from the external iliac vein through the inferior epigastric vein to the superior mesenteric vein and thence to the

Chart 3 Postoperative measures to restore venous circulation

superior vena caval system. In women an additional important deep pathway is found in the ovarian veins which have access to blood from the hypogastric veins through the pelvic and uterine plexuses and deliver it to the inferior vena cava directly or via the renal vein. In men the homologous pathway through the spermatic veins is considerably less efficient, which probably explains the clinical observation that the superficial abdominal veins usually are more prominent in men than in women after ligation of the inferior vena cava. The main superficial collateral circulation is from the femoral vein through the superficial epigastric vein to reach the superior vena cava system by communication with the lateral thoracic vein. Other veins which contribute to the collateral circulation include the vertebral venous system (communication through pelvic plexuses), the lumbar veins (communication through the deep iliac circumflex vein and ilio-lumbar vein) and the superficial iliac circumflex and superficial internal circumflex branches of the femoral vein.

NUTRITIONAL PREPARATION FOR SUBSTANDARD RISK PATIENTS

RICHARD I. VARCO M.D. Minneapolis, Minnesota

THE number of publications which have appeared during the war years and since attest to the current interest among investigators and clinicians, in nutritional problems. As a consequence of these efforts it is now possible to list better methods for solving the dilemma of the surgeon contemplating a major operation on a patient who is a substandard risk as a result of a chronic dietary deficiency. When from unhappy personal experiences, surgeons had learned to calculate the added risks these individuals suffered often in the past, a number were denied benefits obtainable through surgery or if accepted after a genuine appraisal of the increased hazard, the necessary surgical manipulations were found to be poorly tolerated. The patient seemed to react unfavorably from the outset with an instability of blood pressure out of proportion to the actual blood loss. Blood transfusions would often produce only a transient and unsatisfactory response. Frequently the convalescence was protracted, complications developed to jeopardize the patient's life. In a considerable number a vitality sufficient to meet all the requirements for convalescence was so lacking that death occurred. The usual variety of therapeutic measures. The usual autopsy findings of some incipient heart failure and bronchopneumonia, a fatty liver or a failure of wound healing, were hardly an operation but rather confirmed the impression that malnourished individuals presented a substandard risk. Too frequently the issue will continue to be settled tragically if surgeons persist merely in restoring to normal the hydration, electrolyte status, and hemoglobin content. The statement has facetiously been offered that some modern surgeons find it necessary to operate by the calendar while others can 'work by the clock.' However a measure of wisdom may well be with the former when dealing with chronically starved patients because an increased experience with the preoperative phase of dietary preparation indicates that the success of an operation may hinge on the effectiveness of such nutritional care and makes unnecessary the completion of a hasty dissection before the patient's condition deteriorates. Such a statement implies that the pathologic biochemical states resulting from starvation are reversible after an appropriate dietary regimen. In nearly all except premonitory instances this is possible. The rate at which the lost body protein can be replaced is much slower though than when balanced anew the body electrolytes or fluids. Sudden dramatic results which capture the attention are not the rule. The processes of nutritional restitution frequently require days, may even take weeks, and therefore demand of the surgeon patience. In this regard there is a real need as yet unanswered for simple accurate methods of determining how seriously starved the patient actually is, how much nourishment and how long, should he be fed before an operation can be undertaken without an added risk. Fortunately however a partial restoration of the bodily stores usually suffices to permit performance of the necessary operative procedure. That is to say all the fat need not be forced from the liver nor all depleted tissues refabricated nor the hypoproteinemia completely corrected or the immune globulins and phagocytic values restored to normalcy. Even though short of this goal, after a reasonable period of satisfactory preoperative food intake the surgeon can then anticipate a convalescence virtually as free of complications as that encountered among the standard risk group. A discussion of the meth-

From the Department of Surgery, University of Minnesota Medical School, Minneapolis.
The researches upon which this presentation is based were supported by a grant of the Graduate School of the University of Minnesota.
Presented in the Symposium on Care of the Patient before and after Operation, before the Clinical Congress of the American College of Surgeons, December 16-20, 1946.

ods and nutrients employed upon the surgical service at the University of Minnesota Hospitals for realizing this represents the subject matter of this paper. It is hoped that the therapeutic outline offered will prove to have a broad practical application to the several nutritional problems faced by surgeons and by virtue of its relative inexpensiveness, simplicity of preparation and apparent effectiveness, merit trial in the preoperative dietary preparation of surgical patients.

FACTORS RELATED TO LIQUID DIETS FORTIFIED WITH PROTEIN AND CARBOHYDRATES

During semistarvation or starvation periods, man just as any experimental animal becomes autocannibalistic while deriving his energy from body fat and protein. This means that his diet necessarily is low in calories, carbohydrates, and protein but relatively high in fat. From this one might predict that a diet of opposite qualities, namely high in protein carbohydrates and caloric content, would be best suited to correcting those abnormalities ascribable to this starvation regimen. The results of numerous investigations and clinical experience have confirmed this impression.

Of these several constituents experience and experimentation have demonstrated that protein plays a chief rôle. The principal sources of protein in natural foods are meat, fish, eggs, certain dairy products and cereals. Yet, in each of these, the protein contributes but a fraction of the total bulk. It therefore becomes necessary to consume relatively enormous quantities of food when very high protein diets are desired. For example, to realize an intake of 300 grams of protein from beef, a pot roast between 3 and 4 pounds would have to be eaten. This is a feat usually beyond the capacity of any individual weakened and apathetic from prolonged starvation and is an impossibility in the case of those patients with stenosis or obstruction due to a lesion at the pyloric outlet. Desirable as it may be to foster the consumption of a high protein diet by pleasant appearing tastily prepared menus, the physical factors indicated above limit the accomplishments possible by this means. In order to pyramid the intake from such means,

liquid dietary supplements fortified with a protein concentrate and ordinarily also a carbohydrate can be used. A variety of protein concentrates are at present available, and among these is skim milk powder with the following composition:

Components	Per cent
Protein	37.8
Casein	3
Lactalbumin	5.2
Lactoglobulin	3
Carbohydrate (lactose)	49.7
Fat	1
Water	3.0
Ash	3.5

An experience has been acquired with use of this fortifying substance in diets prepared for treating several hundred malnourished surgical patients on the surgical service of the University of Minnesota Hospitals. Skim milk powder has a low cost, is readily and widely available in quantity stores well in the bulk, and can be fairly well disguised in a variety of palatable mixtures. The proteins present are complete, possess a medium capacity to induce plasma protein regeneration under experimental conditions, and are rich in the liver protecting amino acid methionine. In addition much of our biologic information on nutrition has been acquired using those proteins present in skim milk powder. They have repeatedly proved excellent sources when fed in quantity.

The use of a liquid diet either as a supplement to the hospital fare or as the sole source of calories finds frequent and valuable application in the care of patients with surgical lesions of the esophagus, stomach, and duodenum. A tale of recent weight loss can usually be found written in their admission history. This is particularly true when mild or serious degrees of obstruction are an associated complication of the disease process. Here not uncommonly the oft repeated acceptance of an incompletely masticated bolus of solid food leads to an insoluble problem in aboral transport and results in an even greater degree of obstruction and retention. Yet, it has not been unusual to note that when the lumen has been freed of these chunks by repeated washings, very satisfactory volumes of a liquid diet are accepted daily with little or no retention.

VARCO NUTRITIONAL PREPARATION FOR RISK PATIENTS

The fluid character of these liquid mixtures has an appeal for the dietetic staff burdened by a number of requests for special trays. Untrained workers can be easily instructed to perform the simple compoundings involved in the preparation of these formulas. Too the use of liquid diets with a fixed caloric value has made relatively easy and practical the measurement calculation and charting of the daily caloric intake on the same sheet with temperature pulse and respiration. Nutrition is thus brought into focus at the bedside whenever chart rounds are being held. This method of day to day contact with the problem and an accounting of the progress made or lost, is of fundamental importance for the consistently satisfactory care of those classified as substandard risks by virtue of malnourishment. Several diets have been tried but the following with some variations, has appeared most adaptable.

Fig 1 Drip feeding apparatus.

tubing and flow rates are thus visualized and regulated by a thumb screw attachment.

Most patients however are able to drink the mixture and as it is the taste is similar to that of an eggnog. It can of course be flavored to suit the individual desire with chocolate cocoa vanilla or other disguising substances. Some such variation is frequently employed by out patients undergoing dietary preparation. These patients can obtain skim milk powder by prescription from the bulk stock in the drug room. Simple mimeographed directions about preparation volume to be consumed daily, and the refrigeration requirements are given to them during the course of the out patient workup. A brief explanation to this group of the importance to them of this dietary preparation usually suffices to insure their co-operation. Preparation from the out patient approach is frequently possible except in the case of the very debilitated and hence reduces the actual period of hospitalization in many instances to about that for the more standard risk group. Whenever this liquid diet constitutes the sole source of food for the patient, he is urged to take if possible about 5000 calories, i.e. 3 liters daily. In the absence of obstruction this is no great problem and the consumption of quantities greater than this is not unusual. If the diet is used as a supplement, the acceptance of even a liter adds materially to the protein and caloric intake for that day. Diarrhea has been a problem sporadically. It usually can be avoided

Bart, cane sugar or cerelose can be substituted.

This mixture passes readily through an indwelling nasal tube. It can therefore be employed as a drip feeding mixture in an apparatus similar to that in Figure 1. This is employed when caring for persons so enfeebled by their disease and starvation that it is impossible for them to make the efforts necessary to get adequate amounts of food from bedside trays. For this setup it has proved advantageous to use an intravenous flask with a dependent air vent. This permits the entering bubbles as they rise to agitate gently the mixture and hence reduces the tendency to plugging through sedimentation. A Murphy drip apparatus is inserted into the connecting

Diet described

through the maintenance of appropriate refrigeration of all portions of the diet other than the patient's immediate requirements and by the routine use of thoroughly cleansed or sterilized dispensing equipment. Should it occur despite attention to these precautions modest doses of paregoric and amphogel will ordinarily correct the situation. Patients with ulcerative colitis or regional enteritis are rather consistent exceptions to this, however and may develop an aggravatingly persistent diarrhea. The use of this mixture therefore is best avoided or limited to small quantities while testing the patient's tolerance.

As indicated earlier satisfactory objective measurements of the accomplishments of a refeeding regimen are virtually nonexistent. By trial and error methods it has been possible to arrive at estimates of how long a patient should receive a caloric intake augmented to about 4000 or more calories daily. From experiences with several hundred nutritional problems the conclusion has been reached that if 5 to 7 days are devoted to such dietary preparation for each 10 per cent of the body weight lost, the individual will consistently be able to tolerate extensive surgical procedures. These values are admittedly empirical and probably maximal rather than minimal. Until more critical tests are available however the present method offers a reasonably reliable means for calculating the duration of the special dietary regimen.

REASONS FOR DIETARY PREPARATION PREOPERATIVELY

It will be noted that emphasis has been placed upon preparation being preoperative. This appears to be an important consideration because the weight of evidence at this time indicates a greater retention of nitrogen ingested during this phase rather than after an operation. Data from a number of laboratories (2, 4, 7, 10) as well as ours (11) confirm the accelerated loss and difficulty of securing a favorable balance of nitrogen in the recovery phase after surgery. In addition such difficulties are pyramided when the patient after an intestinal operation is unable to take nourishment for several days because of ileus, nausea or vomiting.

OTHER SOURCES OF PROTEIN AVAILABLE FOR SUPPLEMENTING DIETS

Besides skim milk powder various substances are available as fortifying materials. The data of Madden and Whipple (6) suggest a number of possibilities. Two of these homogenized raw pork liver and powdered bovine plasma protein have been tested and each demonstrated (12, 13) to be definitely superior to skim milk powder for the production of protein. Unfortunately the possibility of controlling brucellosis appears too real to permit routine use of the former. The latter so far has been obtainable only in quantities sufficient for investigational purposes despite the fact that countless tons are potentially available in the blood now sold as fertilizer or stock feed. Whereas, estimates of manufacturing costs are high when calculated on the amounts available from a few pilot plants, the application of modern production methods on a larger scale would likely result in price reductions sufficient to permit its less restricted usage. The incentive to develop the manufacturing of this product by the packing industry necessarily will await a more generalized medical recognition of and demand for just such a superior dietary protein. In a similar fashion a large portion of the protein of fresh caught tuna, mackerel and sardines is lost to human consumption (3). This, under current commercial practices, inedible fraction can be separated from its unpalatable characteristics and in this purified form possesses high biological value for hemoglobin and plasma protein formation. These tests limited to date to small animals, might profitably be extended to clinical material. Yeast has received somewhat limited attention as a source of protein for humans due to its rather low content of sulphur containing amino acids and because of an objectionable odor and taste which are quite difficult to disguise. These several drawbacks have been virtually eliminated in products recently developed from new strains (9). The result is a powder virtually free of unpleasant aromatic or gustatory characteristics, with as much as a 70 to 80 per cent protein content. Its effectiveness as a dietary supplement for man remains unmeasured. These to mention but a few con-

VARCO NUTRITIONAL PREPARATION FOR RISK PATIENTS

contributions of biochemists to general nutritional problems offer a partial solution of the search for more, better and cheaper proteins with high biological activity. Their trial in the management of clinical dietary problems assuredly seems warranted if the progress of our knowledge in this field is to parallel that in the laboratory. From the selection of materials now available for fortifying diets broad scope is offered to the investigator in developing those combinations achieving the greatest effectiveness with the least cost and with the best palatability.

METHODS FOR PARENTERAL NUTRITIONAL PREPARATION

In certain nutritional problem cases, fortunately a rather small percentage the oral route is not available for protein and caloric repletion. On a surgical service this most often results from an obstructive lesion of the esophagus, stomach or duodenum which will ultimately require a surgical procedure of magnitude. In this situation the surgeon has essentially two alternatives. For one he can elect to make a jejunostomy for alimentation. My personal experience with this operation has been a limited but rather consistently unsatisfactory one. Despite the employment of a wide variety of mixtures, severe diarrhea has invariably appeared before the quantity of material being fed reached a desirable level. The attainment of a substantial nitrogen and caloric balance under these circumstances is of course unlikely. Even when this complication has been less troublesome convalescence has lagged. This may be related to the well documented temporary inability to anabolize protein that exists after a traumatic episode and which has been carefully studied by several workers *vide supra*. The other alternative is the establishment of a parenteral feeding program for the dual purpose of meeting the patient's current caloric needs, and securing the maximal nitrogen retention possible under the circumstances. To this end a daily carbohydrate intake of 200 to 250 grams is realized through the use of 10 to 20 per cent glucose solutions intravenously and isotonic glucose solutions subcutaneously. Unless this much sugar is available to the body for energy re-

quirements quantities either of the body proteins or of infused nitrogenous compounds continue to be catabolized for fuel. The magnitude of the carbohydrate intake therefore bears an indirect but quite essential relation to the state of the nitrogen balance. Direct control of the state of the nitrogen balance however is regulated by the kind and amount of nitrogenous compounds injected.

A portion of these requirements can be provided by protein hydrolysates or pure amino acid mixtures (5). The latter has not been available so far in this clinic. Several definite limitations exist with the use of the former. Between 15 and 20 hours are required to complete the infusion of six thousand cubic centimeters of 5 per cent each of the protein hydrolysate amigen and of glucose. This is about the maximum quantity acceptable in each 24 hours. If this casein hydrolysate is injected at rates much faster than this or in greater concentrations, unpleasant systemic manifestations in our experience become more frequent. The nitrogen content of this considerable volume of fluid is theoretically equivalent to 225 grams of protein. In some cases with a long history of extreme privation and continuing rapid loss of protein (burns, massive ulceration, etc.) this quantity of nitrogen would scarcely suffice if the entire amount were available for useful metabolic activity.

Actually however in several experiments it has been demonstrated that the total nitrogen content of a 24 hour urine collection after a venoclysis of this type contains considerably more waste nitrogen than that obtained while feeding equivalent amounts of skim milk powder or powdered bovine plasma protein. There are at least two reasonable explanations for these findings. Since differences in biological activity have been demonstrated for proteins from various sources a material superior in all around qualities to casein (i.e. bovine plasma protein) might provide a more utilizable hydrolysate if it were tried as the substrate. Or the hydrolysis by other than intestinal mechanisms, of these substances might lead to a decrease in the acceptability of the end products, perhaps through an incompleteness of processing. The salt content of amigen is of little consequence when only small

through the maintenance of appropriate refrigeration of all portions of the diet other than the patient's immediate requirements and by the routine use of thoroughly cleansed or sterilized dispensing equipment. Should it occur despite attention to these precautions, modest doses of paregonic and amphogel will ordinarily correct the situation. contributions of biochemists to general nutritional problems offer a partial solution of the search for more, better and cheaper proteins with high biological activity. Their trial in the management of clinical dietary problems as surely seems warranted if the progress of our knowledge in this field is to parallel that in the laboratory. From the selection of materials now available for fortifying diets broad scope is offered to the investigator in developing those combinations achieving the greatest effectiveness, with the least cost and with the best palatability.

METHODS FOR PARENTERAL NUTRITIONAL PREPARATION

In certain nutritional problem cases fortunately a rather small percentage the oral route is not available for protein and caloric repletion. On a surgical service this most often results from an obstructive lesion of the esophagus, stomach or duodenum which will ultimately require a surgical procedure of magnitude. In this situation the surgeon has essentially two alternatives. For one he can elect to make a jejunostomy for alimentation. My personal experience with this operation has been a limited but rather consistently unsatisfactory one. Despite the employment of a wide variety of mixtures severe diarrhea has invariably appeared before the quantity of material being fed reached a desirable level. The attainment of a substantial nitrogen and caloric balance under these circumstances is of course unlikely. Even when this complication has been less troublesome convalescence has been less troubled. This may be related to the well documented temporary inability to anabolize protein that exists after a traumatic episode and which has been carefully studied by several workers *vide supra*. The other alternative is the establishment of a parenteral feeding program for the dual purpose of meeting the patient's current caloric needs and securing the maximal nitrogen retention possible under the circumstances. To this end a daily carbohydrate intake of 200 to 250 grams is realized through the use of 10 to 20 per cent glucose solutions intravenously and isotonic glucose solutions subcutaneously. Unless this much sugar is available to the body for energy re-

quirements, quantities either of the body proteins or of infused nitrogenous compounds continue to be catabolized for fuel. The magnitude of the carbohydrate intake therefore bears an indirect but quite essential relationship to the state of the nitrogen balance. Direct control of the state of the nitrogen balance however is regulated by the kind and amount of nitrogenous compounds injected. A portion of these requirements can be provided by protein hydrolysates or pure amino acid mixtures (5). The latter has not been available so far in this clinic. Several definite limitations exist with the use of the former. Between 15 and 20 hours are required to complete the infusion of six thousand cubic centimeters of 5 per cent each of the protein hydrolysate amigen and of glucose. This is about the maximum quantity acceptable in each 24 hours. If this casein hydrolysate is injected at rates much faster than this or in greater concentrations, unpleasant systemic manifestations in our experience become more frequent. The nitrogen content of this considerable volume of fluid is theoretically equivalent to 225 grams of protein. In some cases with a long history of extreme privation and continuing rapid loss of protein (burns, massive ulceration, etc.) this quantity of nitrogen would scarcely suffice if the entire amount were available for useful metabolic activity. Actually however in several experiments it has been demonstrated that the total nitrogen content of a 24 hour urine collection after a venoclysis of this type contains considerably more waste nitrogen than that obtained while feeding equivalent amounts of skim milk powder or powdered bovine plasma protein. There are at least two reasonable explanations for these findings. Since differences in biological activity have been demonstrated for proteins from various sources, a material superior in all around qualities to casein (i.e. bovine plasma protein) might provide a more utilizable hydrolysate, if it were tried as the substrate. Or the hydrolysis by other than intestinal mechanisms of these substances might lead to a decrease in the acceptability of the end products, perhaps through an incompleteness of processing. The salt content of amigen is of little consequence when only small

volumes are being employed but attains real significance (9 grams in 6000 cubic centimeters of 5 per cent solution) when large volumes are in use. This item becomes even more important in the presence of the hypoalbuminemia frequently present in just this type of patient. States of overhydration due to such liberal administrations of salt and serious enough to require temporary cessation of this therapy have been noted.

This listing of these limitations should not be construed to mean that the intravenous administration of protein hydrolysates is fruitless for no one can seriously contend but that it has an important rôle in nitrogen replacement therapy. Rather it is hoped that the recapitulation of such inherent defects will bring their existence to the attention of those who have not so far appreciated them. Fortunately the number of cases wholly dependent on parenteral feeding is in a minority. Such patients must be blessed with the services of conscientious house officer or interne because they demand of him and themselves an abundant patience and tact during the tedious hours of prolonged intravenous therapy. Without actually achieving the goal of large scale plasma protein regeneration those benefits which result from the employment of hydrolysates are certainly real and definitely worthwhile. Through their agency it is possible to halt or retard the steady protein losses from starvation and allied depleting mechanisms (ulceration infection hemorrhage). The nitrogen intake can also be augmented considerably by daily transfusions of plasma or whole blood. Although the total amount of nitrogen in a plasma or whole blood transfusion would be relatively small considered as dietary or hydrolysate nitrogen it is proportionately more valuable because a significantly smaller fraction is lost in the urine the 24 hours after administration. This situation is particularly true when comparison is made with hydrolysate nitrogen. In this connection it appears only fair when calculating the cost of such replacement therapy to base one's ultimate conclusions on the amount of nitrogen the body actually retains and has available for functional purposes, rather than considering solely the price of each intravenous flask

and its contents. The use of whole blood and plasma, particularly when the latter is from a pooled source, is assuredly not an unmixed blessing. The possibility of inoculating the recipient with the virus of infectious hepatitis has been emphasized recently (1, 8) and attention called to this serious hazard.

A nitrogen balance study by my associate, Dr. Arnold Kremen and myself yields data illustrating some of the problems and limitations of parenteral alimentation discussed earlier. The final 5 day period of this study is probably a significant example of the body's greater inclination to accept and retain nitrogen when supplied orally rather than intravenously. As has been indicated, the surgeon will find a knowledge of nutrition a means of improving his care of those patients suffering from a recent serious weight loss. Failure to recognize this obligation and meet the augmented nutritional requirements of this group will be followed by an increase in the morbidity and mortality statistics. To avoid these complications, liquid diets augmented with protein rich materials are recommended whenever the oral route is available. For those patients requiring parenteral feeding a specific program albeit a less satisfactory one, is offered.

COMPLETE OCCLUSION OF THE ABDOMINAL AORTA

Report of Two Patients Diagnosed by Aortography

ALISON HOWE PRICE M.D. and FREDERICK B. WAGNER, Jr. M.D.
Philadelphia, Pennsylvania

IN 2 patients with complete aortic block just below the origin of the renal arteries diagnoses were made during life by direct translumbar aortic injection of radiopaque medium. In 1 patient, the diagnosis was confirmed by 2 subsequent aortograms, while the other was proved at necropsy. The technique used has been described (8-10)

CASE REPORTS

Case 1. T. H., a white man aged 43 years was admitted to Jefferson Hospital on February 8, 1945 with the chief complaint of pain in both ankles. He had been well until October, 1944, at which time he began to experience progressively increasing weakness of both legs with easy fatigability and pain behind the knees on effort.

On December 7, 1944 while eating supper he had a violent periumbilical pain so severe that he became doubled up and broke out in a cold sweat. The pain remained localized to the periumbilical area lasted for 1 hour and was followed by a dull ache which persisted for several days. He was admitted to another hospital. The gastric analysis was normal and a ray study of the upper gastrointestinal tract revealed a small deformity at pyloric end of stomach and was not conclusive of a small ulcer.

While in the hospital 5 days after the first acute episode of pain he experienced a sudden attack of excruciating pain which first involved his right foot and thigh then spread upward to the lower abdomen and finally down the other leg. The attack which lasted about 30 minutes, was accompanied by numbness, paralysis and extreme pallor of both lower extremities. The severe pain then subsided to a dull ache and localized in both ankles. Sensation and motor power returned promptly.

Following discharge from a hospital the patient experienced an almost constant ache in both ankles. The pain usually prevented sleep and necessitated sitting on the edge of the bed with his feet resting on a chair. At the time of admission to Jefferson Hospital he could not take more than 20 steps without experiencing pain in the calves.

From the Department of Medicine and the Samuel D. Gross Surgical Division, Jefferson Medical College Hospital. Presented in the Forum on Fundamental Surgical Problems, before the Clinical Courses of the American College of Surgeons, Cleveland, on a December 6, 20, 1946.

One feature of the occupational history of possible importance was his employment in a cold storage room from 1941 to 1943 during which time he was intermittently exposed to low temperatures.

The patient was thin, weighed 135 pounds and appeared 50 years old. The blood pressure was unrespirable in the lower extremities, but in the left arm was 170/120 and in the right arm 160/120. Eyegrounds showed diffuse arteriolar constriction with increased tortuosity. Several pinpoint hemorrhages and one large hemorrhage in the extreme periphery of the left eye ground. The remainder of the examination of the head as well as the neck and chest, was essentially normal. The aortic pulsations could not be palpated. Arterial pulsations including the femoral, popliteal, posterior tibial and dorsalis pedis, were cold the left colder than the right. Both feet were cold. The erythrocyte count was 4,400,000, hemoglobin 87 per cent, platelets 104,000. The blood sedimentation rate was normal. The blood sugar, urea, Kahn reactions were negative. Results of repeated nitrogen, uric acid and serum proteins were normal. The urea clearance test was 105 per cent and tests of prothrombin time was 100 per cent and both legs revealed hypercoagulability of the blood. Venous pressure in the upper extremities as well as circula-

tion time performed by the calcium gluconate method were normal. The electrocardiogram showed a prominent Q-wave in leads II and III suggesting a prominent Q-wave disease posterior in type. Roentgenograms of the chest, abdomen and spine were essentially normal. Soft tissue examination of the lower extremities failed to show any evidence of calcification in the blood vessels. Study of the upper gastrointestinal tract with barium revealed thickened mucosal folds and slight distortion of the duodenal bulb suggestive of an old healed duodenal ulcer and the barium enema was normal.

Circulatory function tests in the lower extremities all indicated markedly impaired function. Skin surface temperature studies failed to show an appreciable rise after paravertebral lumbar sympathetic nerve block. Peritoneoscopy revealed no evidence of an abdominal mass as a source of extrinsic aortic pressure. The left internal iliac artery and vein were

volumes are being employed but attains real significance (9 grams in 6000 cubic centimeters of 5 per cent solution) when large volumes are in use. This item becomes even more important in the presence of the hypoalbuminemia frequently present in just this type of patient. States of overhydration due to such liberal administrations of salt, and serious enough to require temporary cessation of this therapy have been noted.

This listing of these limitations should not be construed to mean that the intravenous administration of protein hydrolysates is fruitless, for no one can seriously contend but that it has an important rôle in nitrogen replacement therapy. Rather it is hoped that the recapitulation of such inherent defects will bring their existence to the attention of those who have not so far appreciated them. Fortunately the number of cases wholly dependent on parenteral feeding is in a minority. Such patients must be blessed with the services of conscientious house officer or interne because they demand of him and themselves an abundant patience and tact during the tedious hours of prolonged intravenous therapy. Without actually achieving the goal of large scale plasma protein regeneration those benefits which result from the employment of hydrolysates are certainly real and definitely worthwhile. Through their agency it is possible to halt or retard the steady protein losses from starvation and allied depleting mechanisms (ulceration infection hemorrhage). The nitrogen intake can also be augmented considerably by daily transfusions of plasma or whole blood. Although the total amount of nitrogen in a plasma or whole blood transfusion would be relatively small considered as dietary or hydrolysate nitrogen it is proportionately more valuable because a significantly smaller fraction is lost in the urine the 24 hours after administration. This situation is particularly true when comparison is made with hydrolysate nitrogen. In this connection it appears only fair when calculating the cost of such replacement therapy to base one's ultimate conclusions on the amount of nitrogen the body actually retains and has available for functional purposes, rather than considering solely the price of each intravenous flask

and its contents. The use of whole blood and plasma, particularly when the latter is from a pooled source, is assuredly not an unmitigated blessing. The possibility of inoculating the recipient with the virus of infectious hepatitis has been emphasized recently (18) and attention called to this serious hazard.

A nitrogen balance study by my associate Dr. Arnold Kremen and myself yields data illustrating some of the problems and limitations of parenteral alimentation discussed earlier. The final 5 day period of this study is probably a significant example of the body's greater inclination to accept and retain nitrogen when supplied orally rather than intravenously. As has been indicated, the surgeon will find a knowledge of nutrition a means of improving his care of those patients suffering from a recent serious weight loss. Failure to recognize this obligation and meet the augmented nutritional requirements of this group will be followed by an increase in the morbidity and mortality statistics. To avoid these complications, liquid diets augmented with protein rich materials are recommended whenever the oral route is available. For those patients requiring parenteral feeding a specific program albeit a less satisfactory one, is offered.

COMPLETE OCCLUSION OF THE ABDOMINAL AORTA

Report of Two Patients Diagnosed by Aortography

ALISON HOWE PRICE, M.D. and FREDERICK B. WAGNER, Jr. M.D.
Philadelphia, Pennsylvania

IN 2 patients with complete aortic block just below the origin of the renal arteries diagnoses were made during life by direct translumbar aortic injection of radiopaque medium. In 1 patient, the diagnosis was confirmed by 2 subsequent aortograms while the other was proved at necropsy. The technique used has been described (8-10)

CASE REPORTS

Case 1. T. H. A white man aged 43 years was admitted to Jefferson Hospital on February 8, 1945 with the chief complaint of pain in both ankles. He had been well until October, 1944, at which time he began to experience progressively increasing weakness of both legs with easy fatigability and pain behind the knees on effort.

On December 7, 1944 while eating supper he had a violent periumbilical pain so severe that he became doubled up and broke out in a cold sweat. The pain remained localized to the periumbilical area lasted for 1 hour and was followed by a dull ache which persisted for several days. He was admitted to another hospital. The gastric analysis was normal and x-ray study of the upper gastrointestinal tract revealed a small deformity at pyloric end of stomach suggestive but not conclusive of a small ulcer.

While in the hospital 5 days after the first acute episode of pain he experienced a sudden attack of excruciating pain which first involved his right foot and thigh then spread upward to the lower abdomen and finally down the other leg. The attack which lasted about 30 minutes, was accompanied by numbness, paralysis and extreme pallor of both lower extremities. The severe pain then subsided to a dull ache, and localized in both ankles. Sensation and motor power returned promptly.

Following discharge from the hospital, the patient experienced an almost constant ache in both ankles. The pain usually prevented sleep and necessitated sitting on the edge of the bed with his feet resting on a chair. At the time of admission to Jefferson Hospital he could not take more than 20 steps without experiencing pain in the calves.

From the Department of Medicine and the Samuel D. Gross Surgical Division, Jefferson Medical College Hospital. Presented in the forum on Fundamental Surgical Problems, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

One feature of the occupational history of possible importance was his employment in a cold storage room from 1941 to 1943 during which time he was intermittently exposed to low temperatures.

The patient was thin, weighed 135 pounds and appeared 50 years old. The temperature was unobtainable in the lower extremities but in the left arm was 170/120 and in the right arm 160/120. Eyegrounds showed diffuse arteriolar constriction with increased tortuosity of vessels in the extreme periphery of the left eye ground. The remainder of the examination of the head as well as the neck and chest was essentially normal. The abdomen was normal except for the fact that aortic pulsation could not be palpated. Arterial pulsations including the femoral, popliteal, posterior tibial and dorsalis pedis were not palpable in either lower extremity. Both feet were cold, the left colder than right.

The erythrocyte count was 4,400,000, hemoglobin 87 per cent, leucocytes 194,000. The blood sedimentation rate was normal. Results of repeated urine tests were normal. The blood sugar, uric acid, Kahn reactions and serum proteins were normal. The urea clearance test was 105 per cent. The prothrombin time was 100 per cent and both legs revealed hypercoagulability of the blood. Venous pressure in the upper extremities as well as circulatory time performed by the calcium gluconate method were normal. The electrocardiogram showed a prominent Q-wave in leads II and III suggesting coronary artery disease posterior in type.

Röntgenograms of the chest, abdomen and spine were essentially normal. Soft tissue examination of the lower extremities failed to show any evidence of calcification in the blood vessels. Study of the upper gastrointestinal tract with barium revealed thickened mucosal folds and slight distortion of the duodenal bulb suggestive of an old healed duodenal ulcer and the barium enema was normal.

Circulatory function tests in the lower extremities all indicated markedly impaired function. Skin surface temperature studies failed to show an appreciable rise after paravertebral lumbar sympathetic nerve block. Pentotoneoscopy revealed no evidence of an abdominal mass as a source of extrinsic aortic pressure. The left internal iliac artery and vein were

Fig. 1 First aortogram in Case 1 showing complete transverse block of abdominal aorta at level of middle of second lumbar vertebra.

clearly visualized but no arterial pulsation was noted. A neurosurgical consultant reported normal neurologic findings and advised that lumbar sympathectomy would be of questionable value.

Vascular obstruction in the iliac arteries and the aorta itself was thought the most likely possibility but coarctation of the aorta was also considered. It was felt that aortography might definitely prove the diagnosis. Accordingly this procedure was first performed on February 24, 1945, with aortic puncture at the level of the upper border of the first lumbar vertebra. The arteriogram revealed a complete transverse block of the aorta at the level of the middle of the second lumbar vertebra immediately below the origin of both renal arteries (Fig. 1). The renal arteries and their tributaries were well visualized and appeared normal. In order to rule out any errors in technique repeat aortography was performed on April 30, 1945, puncture being made one vertebral level lower, at the upper border of the second lumbar vertebra. On this aortogram (Fig. 2) practically all of the radiopaque medium was visualized within the superior mesenteric artery and its branches and no portion of the aorta itself was definitely delineated. Anastomosis of the middle colic branch of the superior mesenteric artery with the left colic branch of the inferior mesenteric was well demonstrated on this examination. Since the second

Fig. 2 Second aortogram in Case 1 2 months later showing opaque medium within superior mesenteric artery and its branches. Arrow indicates large anastomotic communication between middle colic artery of the superior mesenteric and left colic branch of inferior mesenteric artery.

aortogram merely confirmed the findings of the first one by inference rather than actual demonstration of the block, the study was performed for the third time on June 4, 1945. The needle was introduced at the level of the second lumbar vertebra just above the area of anticipated block. This aortogram (Fig. 3) left no doubt as to the existence of the block, which was sharply delineated at precisely the same level as on the first examination. The large anastomotic channel between the superior and inferior mesenteric arteries was again visualized as well as an extensive paravertebral anastomosis.

Treatment and subsequent course. Anticoagulation therapy with dicoumarol vasodilator drugs (papaverine and nicotinamide sodium citrate and sodium tetrathionate intravenously) and meclochol by sympathectomy and the oscillating bed were employed during his 6½ months in the hospital. One month after admission the patient developed an ischemic ulcer on the lateral aspect of the right leg just above the external malleolus (Fig. 4a). Despite the use of penicillin systemically various local applications including blood ointment and the measures already mentioned to improve the arterial circulation in his lower extremities, the ulcer remained refractory throughout his hospital stay. He

Fig 3 Third aortogram in Case 1, 3 months after first aortography showing sharp delineation of the block just below the origin of the renal arteries. An extensive para-vertebral anastomosis is demonstrated.

Fig 4. Photograph (a, above) shows ischemic ulcer of leg in Case 1 with complete healing (b) 8 months later.

was discharged on August 22, 1945. At this time he could walk about 50 steps before experiencing pain in the calves and he was also able to sleep most of the night without pain in the ankles.

Three months after the patient left the hospital his leg ulcer healed (Fig. 4b) after having been present for 8 months. Follow up examination was last performed on November 26, 1946, a year and 3 months after discharge. At this time the patient stated he felt well, could walk three city blocks without having to stop because of pain and could do light work. Blood pressure in the left arm was 210/150 in the right arm 200/150 but unobtainable in the lower extremities. Aortic pulsation could not be detected and arterial pulsations in the lower extremities were still not palpable.

CASE 2 J. D. a white man aged 52 years was admitted to Jefferson Hospital on February 19, 1945, with the chief complaint of frontal headaches. These headaches which first started in December, 1942, occurred when the patient arose in the morning and became progressively worse during the day. They could be relieved by rest and salicylate medication. In January, 1943 he was informed by a physician that he had albuminuria and a systolic blood pressure of 260. Despite treatment with occasional diuretics,

During the preceding 10 years the patient had experienced numbness, tingling and weakness of the lower extremities particularly after prolonged effort but never any pain. He was treated for pneumococcal pneumonia in February, 1943 in another hospital. The family history was not significant. The patient was a middle-aged thin man weighing 118 pounds, lying comfortably in bed. The temperature pulse and respirations were normal. Blood pressure in the left arm was 250/130 right arm 210/130 left thigh 124/100 and right thigh 130/108. Ophthalmoscopic examination revealed diffuse hypertensive retinitis with arteriosclerosis grade 3. The remainder of the examination of the head as well as the neck and lung fields were essentially normal. The heart was regular in rate, force and rhythm slightly enlarged to the left and there were low grade systolic murmurs at all the valve areas. There was a palpable aortic impulse in the epigastrium over which a systolic murmur was audible but no pulsations could be detected below this area. The remainder of the abdominal examination was normal. Examination of the extremities revealed a full strong radial pulse but arterial pulsations, including femoral, in the lower extremities were almost imperceptible.

The blood count revealed the hemoglobin to be 98 per cent, erythrocytes 5,000,000 and leucocytes 9,800 with normal differential count. The blood sedimentation rate was not increased. The blood Wassermann and Kahn reactions were negative. Repeated urinalyses revealed moderate albuminuria. The highest urine specific gravity was 1.008. The urea clearance test was 64 per cent and the phenolsulfonphthalein dye test revealed 25 per cent

Fig. 5. Aortogram in Case showing complete block at precisely the same level as in Case . Arrow indicates large anastomotic channel between middle colic and left colic arteries as in Figure .

renal excretion in one half hour. The blood urea nitrogen was 20 milligrams. The venous pressure in the arm was 15 millimeters and the circulation time 12 seconds. The electrocardiogram suggested coronary artery insufficiency anterior in type.

A roentgenogram of the chest revealed emphysematous lung fields and a cardiac silhouette within normal limits. There was no notching of the ribs as might be expected with aortic coarctation. X-rays of abdomen and intravenous urogram were normal.

In spite of complete bed rest, sedation and salt poor diet the patient showed no improvement. Even with sodium amyltal narcosis there was no appreciable decrease in hypertension. On March 7, 1945 the patient signed his own release. It was felt that the probable diagnosis was coarctation of the aorta.

The patient was readmitted on March 22, 1945 with the same complaints. The physical examination revealed no significant changes since the last admission. Blood pressure in the left arm was 156/130, right arm, 100/110, left thigh 130/90 and the right thigh 120/90. The blood count and urinalysis revealed essentially the same findings as before. The sedimentation rate was still normal. Another intravenous urogram revealed ptosis of the left kidney.

Because the clinical picture simulated coarctation of the aorta and because roentgenograms of the chest

failed to confirm this belief it was felt that aortography might reveal the exact nature of the lesion. Accordingly this was done on March 23, 1945, puncture being made at the lower border of the twelfth thoracic vertebra. The aortogram (Fig. 5) revealed a sharply defined complete transverse block at the left of the middle of the second lumbar vertebra, just below the origin of the renal arteries. No dye was visualized in the iliac arteries or lower portion of the abdominal aorta. A large anastomotic communication between the middle colic branch of the superior mesenteric artery and left colic branch of inferior mesenteric was well delineated as in Case 1.

The day following aortography the patient was discharged as unimproved.

Following the second discharge the patient came back to his usual work as a waiter. Except for headaches and mild dyspnea on exertion he was able to work until January 28, 1946. At this time he experienced moderately severe substernal pain, radiating down the left arm, accompanied by dyspnea. These symptoms became severe on February 2, 1946 and on February 4 he was admitted to the hospital.

The patient was orthopneic, cyanotic, dehydrated, and poorly nourished. He was drowsy but oriented and co-operative. The temperature was 100° degrees F, pulse 120 and respirations, 36. The blood pressure was 60/110 in the right arm but unobtainable in lower extremities. There were moist rales at both bases but heart sounds were strong; no murmurs noted. There was moderate abdominal distention.

Blood count revealed a hemoglobin of 13.5 per cent, erythrocytes 5,400,000, leucocytes 14,000 with 90 per cent neutrophils, and 10 per cent lymphocytes. Urinalysis revealed occasional granular casts but was otherwise normal. The sedimentation rate was not increased. The blood nonprotein nitrogen was 75 milligrams and carbon dioxide combining power 30 volumes per cent. The electrocardiogram showed changes indicating an acute anterior coronary occlusion with involvement of a large posterior branch. The patient became progressively more dyspneic and died 33 hours later. During this final admission he voided only 200 cubic centimeters of urine.

Postmortem examination was performed by Dr. Peter A. Herbst. The salient gross pathologic findings were generalized arteriosclerosis, bilateral pleural adhesions, pulmonary congestion and edema, terminal pneumonia, cardiac hypertrophy, atherosclerotic thrombosis of the abdominal aorta both old and recent, and bilateral polar renal vessels. The heart, aorta, and kidneys were of the greatest interest and the findings in these are given in some detail.

The heart weighed 555 grams. The pericardial and endocardial surfaces were smooth and glistening. The myocardium was firm, hypertrophied and reddish brown. There was no definite evidence of old or recent infarction. The valves were normal in number, size, shape, and position. Coronary artery patent, and vessels showed moderate atherosclerosis.

The thoracic aorta showed moderate atherosclerosis with several plaques. The abdominal aorta

showed a complete thrombotic occlusion extending from the renal vessels to the common iliac vessels (Fig 6). The proximal 5 centimeters of the thrombus extending equidistant above and below the upper renal vessels, was recent, dark red friable, and only moderately adherent to the wall of the aorta in places. The portion extending from the lower renal vessels to the common iliacs including the proximal 4 centimeters of the right common iliac was dense grayish white, fibrous, firmly adherent and continuous with the wall of the aorta.

The kidneys weighed 130 grams each and measured approximately 12 by 7 by 5 centimeters. The capsules stripped with ease. The external and cut surfaces were deep reddish brown and the demarcations were sharp. There were 2 renal vessels to each kidney (Fig 6). The upper renal vessels were 4 to 5 centimeters in length 7 to 8 millimeters in diameter and patent. The lower renal vessels were 4 to 5 centimeters in length 2 to 3 millimeters in diameter and occluded. The pelves and ureters were normal.

The salient histologic findings were pleural fibrosis, pulmonary congestion and edema, terminal pneumonia, myocardial fibrosis, atherosclerosis and thrombosis of the abdominal aorta, and benign nephrosclerosis.

Histologic sections of the lower portion of each kidney disclosed only slight ischemic atrophy. Sections through the upper portion showed severe congestion, severe arterial and arteriolar sclerosis, hyalinization of the glomeruli, proliferation of the glomerular epithelium and occasional necrosis of the glomerular tufts. Sections of abdominal aorta at level of injection for aortography showed no changes that could be attributed to needle puncture.

DISCUSSION

Visualization of the level and degree of arterial obstruction as well as the amount of collateral circulation following thrombosis and embolism is possible by means of arteriography. Although employed for this purpose in selected instances in the peripheral arteries (9) arteriography for diagnosis of aortic lesions has been practically neglected. According to a review of the literature on thrombosis and embolism of the abdominal aorta by Greenfield in 1943 there were 161 cases on record and in none of these was aortography done to establish the diagnosis during life.

Blakemore (1) produced total occlusion of the aorta just distal to the renal arteries by wiring and electrothermic coagulation of a syphilitic aneurysm in this location. He then performed aortography by direct injection of 70 per cent diodrast solution into the lower thoracic aorta. The roentgenogram which un-

Fig 6 Postmortem specimen of aorta and kidneys in Case 2 showing old thrombus below renal arteries and recent thrombus above renal arteries. Note bilateral polar renal arteries. Death occurred 10 months following aortography.

fortunately was poor because of motion by the patient, nevertheless revealed radiopaque medium within both renal arteries one very large collateral artery going down the right side posteriorly opacification of the aortic bifurcation as evidence of complete obstruction. Farnas (3, 4) by means of retrograde abdominal aortography has demonstrated partial and complete occlusion of aortic cone. So far as we are aware these represent the only previous reports of aortography in thrombotic occlusion.

It is interesting that, although the level of the block was identical in our 2 patients and both had hypertension the symptomatology was different. In the first patient, the symptoms centered about the diminished supply of blood to the lower extremities while in the second the symptoms were principally related to the hypertension. In both symptoms were slow in onset suggestive of a gradually narrowing process, but in the first the acute pain evidently represented completion of occlusion.

Collateral blood supply to the lower extremities in this condition is mainly by anastomosis

Fig. 3. Aortogram in Case showing complete block at precisely the same level as in Case . Arrow indicates large anastomotic channel between middle colic and left colic arteries as in Figure .

renal excretion in one half hour. The blood urea nitrogen was 50 milligrams. The venous pressure in the arm was 5 millimeters and the circulation time 12 seconds. The electrocardiogram suggested coronary artery insufficiency anterior in type.

A roentgenogram of the chest revealed emphysematous lung fields and a cardiac silhouette within normal limits. There was no notching of the ribs as might be expected with aortic coarctation. X rays of abdomen and intravenous urogram were normal.

In spite of complete bed rest, sedation and salt poor diet the patient showed no improvement. Even with sodium amyltal narcosis there was no appreciable decrease in hypertension. On March 7, 1945 the patient signed his own release. It was felt that the probable diagnosis was coarctation of the aorta.

The patient was readmitted on March 22, 1945 with the same complaints. The physical examination revealed no significant changes since the last admission. Blood pressure in the left arm was 136/130, right arm 100/110, left thigh 130/90 and the right thigh 20/90. The blood count and urinalysis revealed essentially the same findings as before. The sedimentation rate was still normal. Another intravenous urogram revealed ptosis of the left kidney.

Because the clinical picture simulated coarctation of the aorta and because roentgenograms of the chest

failed to confirm this belief aortography might reveal the cause. Accordingly this was done (figure being made at the level of the thoracic vertebra). The aorta was a sharply defined, complete block at the level of the middle of the second just below the origin of the renal arteries. The iliac arteries of the abdominal aorta. A large communication between the middle superior mesenteric artery and the inferior mesenteric was well defined.

The day following aortography discharged as unimproved.

Following the second discharge the patient went back to his usual work as a waiter. He had no aches and mild dyspnea on exertion. He worked until January 18, 1946. At that time he experienced moderately severe substernal pain (starting down the left arm accompanied by numbness in the fingers).

These symptoms became severe on February 4, and on February 4, he was admitted to the hospital. The patient was orthopneic, cyanotic, dehydrated and poorly nourished. He was drowsy but cooperative. The temperature was 100°F, pulse 120 and respirations, 36. The blood pressure was 160/110 in the right arm but none in the lower extremities. There were moist rales at the bases, but heart sounds were strong, no murmur noted. There was moderate abdominal distention.

Blood count revealed a hemoglobin of 23.5 per cent, erythrocytes 5,400,000, leukocytes 24,000 with 90 per cent neutrophils and 10 per cent lymphocytes. Urinalysis revealed occasional granular casts but was otherwise normal. The sedimentation rate was not increased. The blood nonprotein nitrogen was 75 milligrams and carbon dioxide combining power 30 volumes per cent. The electrocardiogram showed changes indicating an acute anterior coronary occlusion with involvement of a large posterior branch. The patient became progressively more dyspneic and died 33 hours later. During this final admission he voided only 200 cubic centimeters of urine.

Postmortem examination was performed by Dr. Peter A. Herbut. The salient gross pathologic findings were generalized arteriosclerosis, bilateral pleural adhesions, pulmonary congestion and edema, terminal pneumonia, cardiac hypertrophy, atherosclerotic thrombosis of the abdominal aorta both old and recent, and bilateral polar renal vesicles. The heart, aorta, and kidneys were of the greatest interest and the findings in these are given in some detail.

The heart weighed 555 grams. The pericardial and endocardial surfaces were smooth and glistening. The myocardium was firm, hypertrophied and reddish brown. There was no definite evidence of old or recent infarction. The valves were normal in number, size, shape and position. Coronary ostia patent, and vessels showed moderate atherosclerosis.

The thoracic aorta showed moderate atherosclerosis with several plaques. The abdominal aorta

Fig. 1 Introduction of valvulotome into aorta after placing traction ligature around aorta and stay sutures in periaortic fat

by digital pressure over the opening while the traction ligature was held taut thus bringing the exposed portion of the aorta into the wound and immobilizing it. A specially constructed valvulotome was then manipulated gently into the aortic opening and made to impinge upon the posterior wall of the aorta (Fig. 1). In contact with the latter the instrument was passed proximally within the aorta, its sheath tamponading effectively the wound in the aortic wall until its further progress was arrested within a cusp of the aortic valve. The hooked blade next was forced out of the sheath perforating the cusp in its pendent portion then the valvulotome withdrawn thus dividing the free margin of leaflet (Fig. 2). In this maneuver the instrument was withdrawn as a whole without bringing the blade back into its sheath. Upon withdrawal of the valvulotome hemorrhage from the opening in the aorta immediately be-

Fig. 2 Schematic representation of longitudinal section of aorta showing perforation of valve leaflet. Withdrawal upward of barbed blade divides free margin of cusp.

a problem of considerable magnitude. Its control was attempted by two methods. At the beginning of the experimental studies, closure of the defect by interrupted fine silk sutures placed in the aortic wall was the method employed. This resulted in a high mortality due to failure of the sutures to hold with tearing of the wall thus increasing the size of the wound to such an extent that uncontrollable hemorrhage ensued (Table II). The second procedure was found to be more effective. It consisted of digital tamponade of the bleeding point until the previously placed stay sutures or pursestring suture in the periaortic fat could be tied over an absorbable gelatin sponge which was manipulated beneath the

Fig 5 Beginning introduction of blade into sheath

Fig 6. The valvulotome completely assembled

The valvulotome. The instrument used in producing the valvular defects consisted of two separate parts the first being an exterior brass sheath of graduated conical shape (Fig 4) the smaller diameter being at the distal end the larger at the proximal end. By this arrangement tamponading of the aortic opening occurred as the distal end of the instrument was introduced into the aorta. The second part of the instrument consisted of a barbed blade attached to the end of a long brass handle (Fig 4). The latter upon being introduced into the sheath in the manner of a trocar into a cannula (Fig 5) fitted snugly within the sheath so as to prevent the escape of blood around it. The interior of the sheath contained a circumferential ridge near its distal extremity which arrested further progression of the handle so as to permit only the blade to project from the distal end. Introduction of the sheath into the aorta was accomplished in each instance with the blade pulled up within the sheath so as not to damage the interior of the aorta during the downward progression of the instrument toward the valve leaflet. The blade was thrust out only after the sheath had become engaged within the cusp (Fig 2).

RESULTS

Twenty two animals were subjected to operation. There were 14 survivals and 8 deaths a mortality of 36 per cent (Table I). All deaths occurred either during the operation or immediately thereafter and were due in each instance to severe blood loss from the aortic wound. No attempt was made to replace blood

by transfusion a fact which undoubtedly influenced the outcome in some cases. Table II summarizes the comparative mortality according to techniques employed to control hemorrhage from the aortic opening. In the first 7 animals operated upon stay sutures of fine silk were placed directly in the wall of the aorta instead of in the periaortic fat. Five of these animals died of hemorrhage because the sutures failed to hold cutting through the aortic wall and producing large rents which grew larger as further efforts at direct closure by suturing were made. Fifteen animals were operated upon with only 3 deaths (Table II) using the combination of periaortic fat suture and gelatin sponge tamponade of the bleeding point. A pursestring suture in the fat was found to be superior to interrupted stay sutures. The 3 deaths in the group treated by the fat suture-gelatin sponge technique resulted from hemorrhage incident to one or both of two factors slipping of the sponge from its proper location during closure of the overlying fat and accidental enlargement to an unmanageable extent of the aortic opening during introduction of the valvulotome. The 14 surviving animals were sacrificed at intervals varying from 24 hours to 7 days after

TABLE III—VALVULAR LESIONS PRODUCED IN SURVIVING ANIMALS

Failures, per cent	14

operation. Valvular lesions were found in 12 animals (86%). In 2 animals, no evidence of a valvular defect was noted (Table III). In the latter it is likely that the valvulotome failed to become engaged in a leaflet passing instead into the ventricular chamber during systole. Perforation or laceration of a cusp occurred in 8 animals while in only 4 animals was complete division of the free margin of the leaflet produced (Table III).

DISCUSSION

Of the technical aspects of the procedure described two features deserve special comment: first the effect of simple division of an aortic valve leaflet upon the ultimate course of aortic stenosis in the human and second the gelatin sponge tamponade method of controlling hemorrhage from a wound of the aorta. Regarding the former only hypothetical considerations are permissible from this preliminary report. As noted by Cutler and Beck (9) the presence of marked thickening, rigidity, and calcification in the aortic valve in cases of stenosis would indicate that valvulectomy rather than valvulotomy may be necessary to alter favorably the circulation in these cases. Furthermore an estimate of the effect of either procedure is difficult in the absence of a satisfactory method of producing aortic stenosis in the experimental animal. Further experimentation in this field is indicated.

Concerning the gelatin sponge method of tamponading hemorrhage from the aorta one might regard the technique employed as being relatively insecure. While it would appear that direct suture of the aortic wound is preferable a lower mortality resulted in those

animals treated by the gelatin sponge method. These findings are in keeping with the work of Jenkins (14, 15) and his associates whereby the successful use of absorbable gelatin sponge was demonstrated in controlling hemorrhage from wounds of the heart, aorta, and vena cava in experimental animals.

SUMMARY

With a view toward its possible application to the treatment of aortic stenosis in human subjects, a technique of aortic valvulotomy in dogs is described.

ARTERIOVENOUS FISTULA EXPERIMENTAL STUDY OF INFLUENCE OF SYMPATHETIC NERVOUS SYSTEM ON DEVELOPMENT OF COLLATERAL CIRCULATION

RALPH A DETERLING Jr MD HIRAM E. ESSEX Ph D and
JOHN M WAUGH MD FACS., Rochester Minnesota

UP to the time of John Hunter the ligation of a major vessel had been avoided because it was a fearful procedure in the treatment of aneurysm owing to the high incidence of infection, gangrene and secondary hemorrhage. Not until the early part of the nineteenth century was the concept accepted that collateral vessels were able to take over the function of a major artery in supplying adequate nutrition to the tissues. The high incidence of recurrence of symptoms as well as the development of severe trophic disturbances and gangrene after simple ligation of the artery proximal to the arterial and arteriovenous aneurysm (Aneurysm) led Makins in 1914 to suggest the simultaneous ligation of the companion vein. Further experimental and clinical studies of arteriovenous fistula by Holman (19-21, 23, 24) Reid (40, 43) Pemberton and others (36, 37) have established quadruple ligation and excision of the vascular lesion as an adequate means of treatment. Since a relatively small proportion of cases have been suitable for treatment by the Matas restorative endoarteriomyorrhaphy or the Blakemore Lord type of vein graft, we must be ultimately concerned with the degree of collateral communication between a major artery and vein. Reid (42) in 1925 stated that the arteriovenous fistula is the most powerful stimulus to the development of collateral circulation known and consequently urged that sufficient passage of time should be allowed to permit the development

of adequate collateral circulation. The factor of time has been similarly emphasized by Matas, Holman and by Pemberton and Black (36). Itkin and many others.

It should be pointed out however that an arteriovenous communication acts entirely differently from other types of vascular lesions, which usually cause more or less obstruction with a resulting rise in resistance to the flow of blood through the affected vessels. In an arteriovenous fistula, on the other hand, the blood in the arterial system on arriving at the fistula, enters a region of markedly reduced resistance and flows directly into the vein where its distal movement is obstructed by valves, by the decreasing caliber of the vessels and by the elevated venous pressure. The blood consequently returns immediately to the right side of the heart thus by passing the distal arteriolar and capillary beds. The shunting of the arterial blood when sufficiently great, obviously deprives the distal tissues of the involved part of adequate nutrition and stimulates compensatory responses. To quote Holman (22) "All avenues of approach to the fistula open up to appease as it were the thirst of the fistula." As stated in the preceding paragraph, one important factor in disrupting normal vascular physiologic processes in a part distal to an arteriovenous fistula is the rise of venous pressure. It is obvious that the arterial blood, under a tension of more than 100 millimeters of mercury on entering the venous system via the fistula will cause an elevation of the venous pressure which by contrast normally may be measured as a few centimeters of water. The mechanical obstructions to distal venous flow of this arterial blood mentioned previously are effective in diverting the greater part of the flow proximally toward the heart. This in crease of volume flow and pressure results in a

operation. Valvular lesions were found in 12 animals (86%). In 2 animals, no evidence of a valvular defect was noted (Table III). In the latter it is likely that the valvulotome failed to become engaged in a leaflet, passing instead into the ventricular chamber during systole. Perforation or laceration of a cusp occurred in 8 animals, while in only 4 animals was complete division of the free margin of the leaflet produced (Table III).

DISCUSSION

Of the technical aspects of the procedure described, two features deserve special comment: first, the effect of simple division of an aortic valve leaflet upon the ultimate course of aortic stenosis in the human; and second, the gelatin sponge tamponade method of controlling hemorrhage from a wound of the aorta. Regarding the former, only hypothetical considerations are permissible from this preliminary report. As noted by Cutler and Beck (9), the presence of marked thickening, rigidity, and calcification in the aortic valve in cases of stenosis would indicate that valvulectomy, rather than valvulotomy, may be necessary to alter favorably the circulation in these cases. Furthermore, an estimate of the effect of either procedure is difficult in the absence of a satisfactory method of producing aortic stenosis in the experimental animal. Further experimentation in this field is indicated.

Concerning the gelatin sponge method of tamponading hemorrhage from the aorta, one might regard the technique employed as being relatively insecure. While it would appear that direct suture of the aortic wound is preferable, a lower mortality resulted in those

animals treated by the gelatin sponge method. These findings are in keeping with the work of Jenkins (14, 15) and his associates whereby the successful use of absorbable gelatin sponge was demonstrated in controlling hemorrhage from wounds of the heart, aorta, and vena cava in experimental animals.

SUMMARY

With a view toward its possible application to the treatment of aortic stenosis in human subjects, a technique of aortic valvulotomy in dogs is described.

ARTERIOVENOUS FISTULA EXPERIMENTAL STUDY OF INFLUENCE OF SYMPATHETIC NERVOUS SYSTEM ON DEVELOPMENT OF COLLATERAL CIRCULATION

RALPH A DETERLING Jr M.D. HIRAM E. ESSEX Ph.D. and
JOHN M. WAUGH M.D. F.A.C.S. Rochester Minnesota

UP to the time of John Hunter the ligation of a major vessel had been avoided because it was a fearful procedure in the treatment of infection gangrene and secondary hemorrhage. Not until the early part of the nineteenth century was the concept accepted that collateral vessels were able to take over the function of a major artery in supplying adequate nutrition to the tissues. The high incidence of recurrence of symptoms as well as the development of severe trophic disturbances and gangrene after simple ligation of the artery proximal to the arterial and arteriovenous aneurysm (Anel ligation) led Makins in 1914 to suggest the simultaneous ligation of the companion vein. Further experimental and clinical studies of arteriovenous fistula by Holman (19-21, 23, 24) Reid (40, 43) Pemberton and others (36, 37) have established quadruple ligation and excision of the vascular lesion as an adequate means of treatment. Since a relatively small proportion of cases have been suitable for treatment by the Matas restorative endoaneurysmorrhaphy or the Blakemore-Lord type of vein graft, we must be ultimately concerned with the degree of collateral communication between a major artery and vein. Reid (42) in 1925 stated that the arteriovenous fistula is the most powerful stimulus to the development of collateral circulation known and consequently urged that sufficient passage of time should be allowed to permit the development

of adequate collateral circulation. The factor of time has been similarly emphasized by Matas Holman, and by Pemberton and Black (36) Elkin and many others.

It should be pointed out, however, that an arteriovenous communication is a fundamentally different from other types of vascular lesions which usually cause more or less obstruction with a resulting rise in resistance to the flow of blood through the affected vessel. In an arteriovenous fistula, on the other hand, the blood in the arterial system, arriving at the fistula, enters a region of markedly reduced resistance and flows directly into a vein where its distal movement is opposed by valves by the decreasing caliber of the vessels and elevated venous pressure. The blood consequently returns immediately to the right side of the heart, thus by-passing the distal arterial and capillary beds. In the event of the blood when sufficient to treat, obviously deprives the distal tissue of the involvement of adequate nutrition and the involved tissue gives rise to Holman's characteristic responses. The arterial pressure falls, as it does in the fistula, and the venous pressure rises, as it does in the fistula, and the tissue becomes anoxic.

As stated in the introduction, an important factor in the development of collateral circulation is the physiologic pressure in the arterial system. It is well known that the pressure in the arterial system is a function of the resistance to the flow of blood. In the case of an arteriovenous fistula, the resistance to the flow of blood is decreased, and the pressure in the arterial system is increased. This increase in pressure is the stimulus to the development of collateral circulation. The degree of increase in pressure is a function of the size of the fistula and the resistance to the flow of blood in the collateral vessels. The degree of increase in pressure is also a function of the time allowed for the development of collateral circulation. The degree of increase in pressure is also a function of the degree of ligation of the artery and vein.

ARTERIOVENOUS FISTULA EXPERIMENTAL STUDY OF INFLUENCE OF SYMPATHETIC NERVOUS SYSTEM ON DEVELOPMENT OF COLLATERAL CIRCULATION

RALPH A. DETERLING, Jr. M.D. HIRAM E. ESSEX, Ph.D. and
JOHN M. WAUGH, M.D., F.A.C.S. Rochester, Minnesota

UP to the time of John Hunter the ligation of a major vessel had been avoided because it was a fearful procedure in the treatment of infection until the early part of the nineteenth century when the concept accepted that collateral vessels were able to take over the function of a major artery in supplying adequate nutrition to the tissues. The high incidence of recurrence of symptoms, as well as the development of severe trophic disturbances and gangrene, after simple ligation of the artery proximal to the arterial and arteriovenous aneurysm (Anel ligation) led Makins in 1914 to suggest the simultaneous ligation of the companion vein. Further experimental and clinical studies of arteriovenous fistula by Holman (19-21, 23, 24) Reid (40, 43) Pemberton and others (36, 37) have established quadruple ligation and excision of the vascular lesion as an adequate means of treatment. Since a relatively small proportion of cases have been suitable for treatment by the Matas restorative endoarteriomyorrhaphy or the Blakemore-Lord type of vein graft, we must be ultimately concerned with the degree of collateral circulation that results from an abnormal communication between a major artery and vein. Reid (42) in 1925 stated that the arteriovenous fistula is the most powerful stimulus to the development of collateral circulation known, and consequently urged that sufficient passage of time should be allowed to permit the development

of adequate collateral circulation. The factor of time has been similarly emphasized by Matas, Holman and by Pemberton and Black (36) Elkin and many others.

It should be pointed out, however, that an arteriovenous communication acts entirely differently from other types of vascular lesions, which usually cause more or less obstruction with a resulting rise in resistance to the flow of blood through the affected vessels. In an arteriovenous fistula on the other hand the blood in the arterial system on arriving at the fistula enters a region of markedly reduced resistance and flows directly into the vein where its distal movement is obstructed by valves, by the decreasing caliber of the vessels and by elevated venous pressure. The blood consequently returns immediately to the right side of the heart thus by passing the distal arteriolar and capillary beds. The shunting of the arterial blood, when sufficiently great obviously deprives the distal tissues of the involved part of adequate nutrition and stimulates compensatory responses. To quote Holman (22) 'All avenues of approach to the fistula open up to appease, as it were the thirst of the fistula.'

As stated in the preceding paragraph, one important factor in disrupting normal vascular physiologic processes in a part distal to an arteriovenous fistula is the rise of venous pressure. It is obvious that the arterial blood, under a tension of more than 100 millimeters of mercury on entering the venous system via the fistula will cause an elevation of the venous pressure which by contrast normally may be measured as a few centimeters of water. The mechanical obstructions to distal venous flow of this arterial blood, mentioned previously, are effective in diverting the greater part of the flow proximally toward the heart. This increase of volume flow and pressure results in a

compensatory dilatation which is demonstrable in the centripetal venous channels as well as the right side of the heart. Distally in the extremity this elevated venous pressure also hinders circulation from collateral vessels that otherwise would be much more effective.

The presence of a region of markedly elevated venous pressure at the fistula serves to act as a block to the venous outflow of the distal parts by virtue of the pressure differential as well as the effect of keeping the distal valves in the veins shut. Since the normal direction of the arterial systolic thrust is centrifugal there is maintained a constant piston-like force on the distal venous tree so that eventually as a result of the distention of the vessels and the direct pressure on the cusps, the valves may become incompetent. The magnitude of this effect depends primarily on the duration, size and location of the fistula. Secondary to this interference with normal venous drainage is an increase of the intercellular fluid and lymph. The scarring about a traumatic fistula may block some of the major lymphatic channels and thus contribute to the formation of edema.

Hence in the presence of a fistula, the distal parts are frequently deprived more effectively of a normal circulation than following actual ligation of the major artery or arterectomy. That the so-called collateral circulation is unable to provide an adequate blood supply to the tissues is evidenced by the frequent occurrence of trophic alterations in the distal parts. Trophic changes are seen as well in persons who have congenital arteriovenous fistulas even when the maximal time for development of collateral circulation has elapsed. While gangrene is relatively rare following closure of an arteriovenous fistula in the lower extremity there is a high incidence of vascular insufficiency particularly in the aged which is manifested by chronic edema, intermittent claudication, ease of fatigue, sensation of heaviness and paresthesias. This was noted by Bigger who saw in his postoperative cases definite evidence that circulation is inadequate for sustained muscular activity. This is an important matter and one which has not received the attention which is its due. Other authors have seen fit to question the value of this type

of vascular response. La Roque in 1921 expressed the opinion that there was "much reason for believing that the development of circulation is antagonized by arteriovenous fistula. Elkin (8) in 1943 similarly pointed out the possible inadequacy of this collateral circulation when he said that this great collateral circulation was for the most part useless since the blood returns to the heart without nourishing the distal parts. Recently Freeman has called further attention to the vascular deficiency which may follow the surgical repair of arteriovenous fistulas. In the March 8, 1947 issue of the *Journal of the American Medical Association* Hennigman, Rives and Davis reviewed the results of the various operative procedures employed in a series of 53 cases of arteriovenous fistula. Local vascular insufficiency did not develop in any of the 8 patients treated by a restorative procedure whereas a third or more of those patients having an obliterative procedure suffered subsequently from the symptoms of vascular deficiency.

The acceptance by so many surgeons of the concept that great collateral circulation develops with time generally has resulted in a delay of 3 to 6 months in the treatment of arteriovenous fistulas. Consequently we were stimulated to attempt to determine the actual effective arterial collateral circulation present in a limb which had had a fistula functioning for periods of time up to one year. Furthermore, because of the claim of some investigators that attempts to improve collateral circulation (after time enough has elapsed for it to have developed) are foolhardy if not actually contraindicated, an investigation was made of the cutaneous temperature in the limb distal to a long standing arteriovenous fistula, both before and after lumbar sympathetic gangliectomy.

I. DEMONSTRATION OF COLLATERAL CIRCULATION IN A LIMB IN WHICH THERE IS A CHRONIC ARTERIOVENOUS FISTULA

Method. In 19 adult dogs under ether anesthesia, lateral arteriovenous fistulas were made, in the femoral vessels, 1 to 2 centimeters below the profundus branch of the artery by the suture method (7). The communication between the artery and the vein ranged from 1.5

Fig. 3. a, left, Two weeks after bilateral lumbar sympathectomy, showing the isolated arterial collateral circulation (made immediately after excision of a fistula of 7½ months' duration). b, Two weeks after unilateral lumbar sympathectomy performed on the side of the fistula (left). In this case the picture was taken immediately after excision of a fistula of 7½ months' duration.

isolated arterial tree with the complete arterio-venous bed.

Group III Method.—The legs of the 4 remaining animals of series A were perfused in the usual manner and the fistula was dissected free. Carrel clamps were placed on the proximal and distal vessels to occlude the arterio-venous communication effectively. Injection was then carried out and roentgenograms of the isolated arterial circulation were made. Later the clamps were released and the injection of the barium mass was completed as in group I. Roentgenograms were again taken.

Results.—This set of experiments showed clearly the paucity of arterial collateral circulation compared with the total vascular bed in the region of the fistula (Fig. 2a and b) in the same animal. A differential study of this kind in a group of animals having comparable fistulas of varying duration makes possible an understanding of the rate of development of the vascular changes. It is evident that the arterial response appears very rapidly reaching its maximal development early while the augmentation of the venous system is gradual, occurring during a period of many weeks.

Series B Method.—The remaining 7 animals were also used in a study of the effect of lumbar sympathectomy on blood flow and cutaneous temperature. In 4 animals, bilateral lumbar ganglionectomy was performed and in 3 the ganglionectomy was restricted to the side of the fistula. In all the animals, the arteriovenous communication had been active for about 7 months before sympathectomy. In this series the fistula was excised 2 weeks after sympathectomy (a) to demonstrate further the isolated arterial system as an entity and (b) to show any effect on this system that sympathectomy might have had. Immediately after the quadruple ligation and excision of the fistula, the injection of the isolated arterial tree was carried out as described for group II.

Results.—Roentgenograms were made of the lower arterial vascular bed of the sympathectomized animals after perfusion and injection. In the group on which bilateral lumbar ganglionectomy had been performed 2 weeks previous to the excision of the fistula there was a minor degree of vasodilatation and tortuosity of the small arteries just distal to

Fig. a, left, Isolated arterial collateral circulation after occlusion of the abnormal communication with Carrel clamps. b The same animal after removal of the clamps and completion of the injection with the fistula patent. This indicates that the predominant vascular response has been venous.

crease of venous pressure and blood flow. This

'Medusa's head' in the region of the fistula is what many authors have referred to when they described the collateral circulation of an arteriovenous fistula. This is also an example of what one sees in a clinical angiogram of this type of lesion for the patent communication allows the contrast medium to fill the entire network of vessels and permits identification of the fistula. It must be realized that a clear picture of the arterial circulation is necessary to evaluate collateral circulation. Any obliterative surgical procedure will close the communication between the artery and the vein, and consequently exclude the dilated venous vessels from the collateral vascular supply. To demonstrate the isolated arterial bed, the following procedure was used.

Group II. Method.—In 4 animals the perfusion with Ringer's solution was carried out as described. The fistula was then exposed by cautious dissection without sacrifice of any major collateral vessel. The proximal artery and vein were identified and ligated adjacent to the site of the fistula. The distal vessels were similarly ligated and the fistula was excised. In all instances the arteriovenous com-

munication had been patent up to the time of closure. Injection was then carried out to demonstrate the arterial system alone.

Results.—In this series, a representation of the venous response to the presence of a chronic arteriovenous fistula was eliminated completely by excision of the fistula. The injected vessels represented only the arterial channels in the limb. These in turn were the true collateral circulation or that part of the circulation which would function after surgical closure of the fistula (Fig. 1b). The marked contrast in the appearance of the vessels before and after closure of the arteriovenous fistula cannot be overemphasized. However, it must be admitted that there was a marked difference in the appearance of the injected vascular beds of successive animals. In some of the animals, except for the region from which the fistula had been excised, the arterial tree was approximately the same in the control limb as in that with the fistula. On the other hand, a number of animals that had fistulas of the same size and duration had a definite augmentation of arterial circulation just distal to the fistula. With such variation possible, it was therefore necessary to compare in the same animal the

the region of the aneurysm (Fig 3a) This was seen also in the series without sympathectomy and represents the degree of arterial response primarily as a result of time As the denervation had been bilateral, there was no significant gross difference in the general vascular bed of both limbs beyond that resulting from the aneurysm alone. The differences of cutaneous temperature of the limbs found are reported farther on in this paper They were accounted for on the basis of differences in the circulation supplying the limbs.

In the animals which had sympathectomy only on the side of the fistula, there was a slight increase in diameter of the vessels on the denervated side over that of the control side. In all these animals, the greatest apparent increase was in the region just distal to the excised fistula (fig 3b) since here there were superimposed the outlines of those many small arteries which had dilated as a result of the aneurysm. However further evidence that the vasodilatation following sympathectomy affected the entire vascular segment will be presented in the section of this report dealing with cutaneous temperature.

Comment A comparison of roentgenograms taken on animals having arteriovenous fistulas of shorter duration than the fistulas of the dogs already considered indicates that the arterial response is rapid requiring only a few days to be significant. This is in agreement with studies on the development of collateral flow by other investigators which have shown most of the channels involved in collateral circulation to be present at the time of an obstruction of a major vessel. The venous component of the circulation resulting from an arteriovenous fistula, on the other hand develops more slowly and relentlessly over a period of weeks or months, and is without beneficial effect on the limb Concurrent with the local dilatation of the venous bed there are increases of circulating blood volume and cardiac size. Experimentally we have found microscopic evidence that there are pulmonary renal, cardiac and hepatic changes which may or may not be reversible.

On inspection of the arterial collateral circulation developed during a period of more than six months, it is important to note that

the localized region of increased vascularization is actually *distal* to the arteriovenous fistula. It would appear therefore that the small arteries, visualized by injection methods, had been subjected to an excessive function, but in a manner different from the usual collateral channels which develop in response to an obstructive lesion. The tremendous return flow of blood from the fistula toward the heart indicates that the dilated channels in the arterial system have been draining blood into the site of the fistula with its low pressure by diversion of much of the blood which flows normally to the pelvic structures and limb via anastomotic channels of the deep circumflex iliac, internal and external iliac, pudendal, gluteal and lateral sacral vessels among others. One may consider as well the possibility that when reversed venous flow occurs, some of this blood finds itself back in arterial channels, and by retrograde flow again enters the site of the fistula. Consequently with the fistula patent, these channels do not serve to by pass the lesion and act as supplementary vessels as in obstructive vascular lesions. In the latter by contrast, the accessory vessels have their greatest function and are the most numerous in the actual region of obstruction. They arise from the immediately adjacent derivatives of the affected vessels, particularly from the proximal branches. Consequently it is difficult to escape the belief that the arterial collateral circulation in the presence of an arteriovenous fistula may contribute much less to the subsequent viability of the limb after obliterative operation than is ordinarily believed. The rise of cutaneous temperature of the toes observed (5.4°) after closure of a more proximal fistula is but a qualitative and not a quantitative index of the increase of distal blood flow. Consequently this rise of cutaneous temperature gives no indication of the actual amount of collateral circulation. That this increase of blood flow may be inadequate is attested by the reports of gangrene and circulatory deficiency following the repair of a fistula.

One would expect the beneficial effects of lumbar sympathetic block on collateral circulation to involve the entire limb in contrast to the response of the vessels to time alone, in which latter case the dilatation would very

DETERLING ET AL. ARTERIOVENOUS FISTULA

probably be localized in the region of the fistula. To test this concept, as well as to determine the degree of influence that the sympathetic nervous system has on a limb subjected to the physiologic changes attending an arteriovenous fistula of long standing we made studies on cutaneous temperatures as an indirect index of digital arterial blood flow

II. STUDIES OF CUTANEOUS TEMPERATURES OF ANIMALS HAVING CHRONIC ARTERIOVENOUS FISTULAS BEFORE AND AFTER LUMBAR SYMPATHECTOMY

Experimental studies (6, 11, 45, 46) have proved that under certain conditions the cutaneous temperature of the paw of an animal may be taken as an indication of the distal arterial blood flow. Consequently alterations of significant magnitude following sympathetic denervation should similarly serve as an acceptable indirect index of blood flow.

Methods: Two recording devices were employed in the measurement of cutaneous temperatures: (1) the Tycoos dermaterm a galvanometric apparatus with thermocouples adaptable to flat skin surfaces and (2) a mercury-bulb chemical thermometer used for measuring the temperature between the toes of the animal. Readings were taken in triplicate and careful control of the environmental variables was exercised as advocated by Sheard (45) and Roth. A constant air temperature of 26 degrees C. was maintained and the humidity was kept at 40 per cent. Linear air movement was limited to 15 to 30 feet (4.6 to 9 meters) per minute. The skin surface was always dry clean and smooth shaven. The animals were kept comfortably recumbent for one hour to allow adjustment of the vasomotor system to a constant temperature. They were fasted 18 hours to exclude metabolic effects and the readings were taken at the same hour each morning to avoid diurnal variation.

These studies were performed on the same group of 19 animals used for the arteriographic studies already described. During the 8 to 10 month period of observation the increase of circulating blood volume (average increase of 31 per cent) and heart size (average increase of 32.5 per cent) was noted. Together with the signs of arteriovenous fistula—vibratory con-

tinuous thrill, machinery murmur, distended pulsating venous channels, bradycardiac reflex, and so forth—there was adequate evidence that the fistula was patent during the entire time.

Results: The average normal temperature gradient as determined by cutaneous thermocouple readings on the medial aspect of the hind leg of a normal animal, from Poupart's ligament to the toes, was recorded. These values are those obtained on the control or right hind limb of the animals having left femoral arteriovenous fistulas (Table I a). From a temperature of 37.0 degrees C. obtained at the groin of the normal limb there was a gradual decrease distally to 31.5 degrees C. as measured in the interdigital web of the foot. On the leg with the fistula the temperatures ranged from 37.5 degrees C. at the groin to 30.0 to 30.5 degrees C. at the toes. In this limb, however, the thigh was warmer than proximally in the groin because of the presence of the aneurysm (38.5° C.). This effect by virtue of increased vascularity in the region of the aneurysm has been utilized clinically to localize a fistula. The great distention of superficial vessels made this entire thigh warmer than on the control side but there was a rather sharp decrease of temperature of the ankle and foot to a value below that of the normal side.

the region of the aneurysm (Fig 3a). This was seen also in the series without sympathectomy and represents the degree of arterial response primarily as a result of time. As the denervation had been bilateral, there was no significant gross difference in the general vascular bed of both limbs beyond that resulting from the aneurysm alone. The differences of cutaneous temperature of the limbs found are reported farther on in this paper. They were accounted for on the basis of differences in the circulation supplying the limbs.

In the animals which had sympathectomy only on the side of the fistula there was a slight increase in diameter of the vessels on the denervated side over that of the control side. In all these animals, the greatest apparent increase was in the region just distal to the excised fistula (fig 3b) since here there were superimposed the outlines of those many small arteries which had dilated as a result of the aneurysm. However further evidence that the vasodilatation following sympathectomy affected the entire vascular segment will be presented in the section of this report dealing with cutaneous temperature.

Comment. A comparison of roentgenograms taken on animals having arteriovenous fistulas of shorter duration than the fistulas of the dogs already considered indicates that the arterial response is rapid requiring only a few days to be significant. This is in agreement with studies on the development of collateral flow by other investigators which have shown most of the channels involved in collateral circulation to be present at the time of an obstruction of a major vessel. The venous component of the circulation resulting from an arteriovenous fistula, on the other hand develops more slowly and relentlessly over a period of weeks or months, and is without beneficial effect on the limb. Concurrent with the local dilatation of the venous bed there are increases of circulating blood volume and cardiac size. Experimentally we have found microscopic evidence that there are pulmonary renal cardiac and hepatic changes which may or may not be reversible.

On inspection of the arterial collateral circulation developed during a period of more than six months, it is important to note that

the localized region of increased vasculature is actually *distal* to the arteriovenous fistula. It would appear therefore that the small arteries, visualized by injection methods, had been subjected to an excessive function, but in a manner different from the usual collateral channels which develop in response to an obstructive lesion. The tremendous return flow of blood from the fistula toward the heart indicates that the dilated channels in the arterial system have been draining blood into the site of the fistula with its low pressure by diversion of much of the blood which flows normally to the pelvic structures and limb via anastomotic channels of the deep circumflex iliac, internal and external iliac, pudendal, gluteal and lateral sacral vessels among others. One may consider as well the possibility that when reversed venous flow occurs, some of this blood finds itself back in arterial channels, and by retrograde flow again enters the site of the fistula. Consequently with the fistula patent, these channels do not serve to bypass the lesion and act as supplementary vessels as in obstructive vascular lesions. In the latter by contrast the accessory vessels have their greatest function and are the most numerous in the actual region of obstruction. They arise from the immediately adjacent derivatives of the affected vessels, particularly from the proximal branches. Consequently it is difficult to escape the belief that the arterial collateral circulation in the presence of an arteriovenous fistula may contribute much less to the subsequent viability of the limb after obliterative operation than is ordinarily believed. The rise of cutaneous temperature of the toes observed (5.41) after closure of a more proximal fistula is but a qualitative and not a quantitative index of the increase of distal blood flow. Consequently this rise of cutaneous temperature gives no indication of the actual amount of collateral circulation. That this increase of blood flow may be inadequate is attested by the reports of gangrene and circulatory deficiency following the repair of a fistula.

One would expect the beneficial effects of lumbar sympathetic block on collateral circulation to involve the entire limb in contrast to the response of the vessels to time alone, in which latter case the dilatation would very

II. STUDIES OF CUTANEOUS TEMPERATURES OF ANIMALS HAVING CHRONIC ARTERIOVENOUS FISTULAS BEFORE AND AFTER LUMBAR SYMPATHECTOMY

Experimental studies (6, 11, 45, 46) have proved that under certain conditions the cutaneous temperature of the paw of an animal may be taken as an indication of the distal arterial blood flow. Consequently alterations of significant magnitude following sympathetic denervation should similarly serve as an acceptable indirect index of blood flow.

Methods. Two recording devices were employed in the measurement of cutaneous temperatures: (1) the Tycoos dermaterm a galvanometric apparatus with thermocouples adaptable to flat skin surfaces and (2) a mercury bulb chemical thermometer used for measuring the temperature between the toes of the animal. Readings were taken in triplicate and careful control of the environmental conditions was exercised as advocated by Sheard (45) and Roth. A constant air temperature of 26 degrees C. was maintained and the humidity was kept at 40 per cent. Linear air movement was limited to 15 to 30 feet (4.6 to 9 meters) per minute. The skin surface was always dry clean and smooth shaven. The animals were kept comfortably recumbent for one hour to allow adjustment of the vasomotor system to a constant temperature. They were fasted 18 hours to exclude metabolic effects and the readings were taken at the same hour each morning to avoid diurnal variation.

These studies were performed on the same group of 19 animals used for the arteriographic studies already described. During the 8 to 10 month period of observation the increase of circulating blood volume (average increase of 31 per cent) and heart size (average increase of 32.5 per cent) was noted. Together with the signs of arteriovenous fistula—vibratory con-

tinuous thrill machinery murmur, distended pulsating venous channels, bradycardiac reflex, and so forth—there was adequate evidence that the fistula was patent during the entire time.

Results. The average normal temperature gradient as determined by cutaneous thermocouple readings on the medial aspect of the hind leg of a normal animal from Poupart's ligament to the toes was recorded. These values are those obtained on the control or right hind limb of the animals having left femoral arteriovenous fistulas (Table I a). From a temperature of 37.0 degrees C. obtained at the groin of the normal limb there was a gradual decrease distally to 31.5 degrees C. as measured in the interdigital web of the foot. On the leg with the fistula the temperatures ranged from 37.5 degrees C. at the groin to 30.0 to 30.5 degrees C. at the toes. In this limb however the thigh was warmer than proximally in the groin because of the presence of the aneurysm (38.5° C.). This effect by virtue of increased vascularity in the region of the aneurysm has been utilized clinically to localize a fistula. The great distention of superficial vessels made this entire thigh warmer than on the control side but there was a rather sharp decrease of temperature of the ankle and foot to a value below that of the normal side.

the region of the aneurysm (Fig 3a) This was seen also in the series without sympathectomy and represents the degree of arterial response primarily as a result of time As the denervation had been bilateral, there was no significant gross difference in the general vascular bed of both limbs beyond that resulting from the aneurysm alone. The differences of cutaneous temperature of the limbs found are reported farther on in this paper They were accounted for on the basis of differences in the circulation supplying the limbs.

In the animals which had sympathectomy only on the side of the fistula, there was a slight increase in diameter of the vessels on the denervated side over that of the control side. In all these animals, the greatest apparent increase was in the region just distal to the excised fistula (fig 3b) since here there were superimposed the outlines of those many small arteries which had dilated as a result of the aneurysm. However further evidence that the vasodilatation following sympathectomy affected the entire vascular segment will be presented in the section of this report dealing with cutaneous temperature.

Comment: A comparison of roentgenograms taken on animals having arteriovenous fistulas of shorter duration than the fistulas of the dogs already considered indicates that the arterial response is rapid requiring only a few days to be significant. This is in agreement with studies on the development of collateral flow by other investigators which have shown most of the channels involved in collateral circulation to be present at the time of an obstruction of a major vessel. The venous component of the circulation resulting from an arteriovenous fistula, on the other hand develops more slowly and relentlessly over a period of weeks or months, and is without beneficial effect on the limb. Concurrent with the local dilatation of the venous bed there are increases of circulating blood volume and cardiac size. Experimentally we have found microscopic evidence that there are pulmonary renal cardiac and hepatic changes which may or may not be reversible.

On inspection of the arterial collateral circulation developed during a period of more than six months, it is important to note that

the localized region of increased vascularization is actually *distal* to the arteriovenous fistula. It would appear therefore that the small arteries, visualized by injection methods, had been subjected to an excessive function, but in a manner different from the usual collateral channels which develop in response to an obstructive lesion. The tremendous return flow of blood from the fistula toward the heart indicates that the dilated channels in the arterial system have been draining blood into the site of the fistula with its low pressure by diversion of much of the blood which flows normally to the pelvic structures and limb via anastomotic channels of the deep circumflex iliac, internal and external iliac, pudendal, gluteal and lateral sacral vessels among others. One may consider as well the possibility that when reversed venous flow occurs, some of this blood finds itself back in arterial channels, and by retrograde flow again enters the site of the fistula. Consequently with the fistula patent, these channels do not serve to by-pass the lesion and act as supplementary vessels as in obstructive vascular lesions. In the latter by contrast, the accessory vessels have their greatest function and are the most numerous in the actual region of obstruction. They arise from the immediately adjacent derivatives of the affected vessels, particularly from the proximal branches. Consequently it is difficult to escape the belief that the arterial collateral circulation in the presence of an arteriovenous fistula may contribute much less to the subsequent viability of the limb after obliterative operation than is ordinarily believed. The rise of cutaneous temperature of the toes observed (5.41) after closure of a more proximal fistula is but a qualitative and not a quantitative index of the increase of distal blood flow. Consequently this rise of cutaneous temperature gives no indication of the actual amount of collateral circulation. That this increase of blood flow may be inadequate is attested by the reports of gangrene and circulatory deficiency following the repair of a fistula.

One would expect the beneficial effects of lumbar sympathetic block on collateral circulation to involve the entire limb in contrast to the response of the vessels to time alone, in which latter case the dilatation would very

Fig 5. Cutaneous temperature of the toes of the normal foot and of the leg with the fistula, 7 months after its production, in addition to rectal and air temperatures: *a*, response to light ether anesthesia; *b*, deep ether anesthesia and concurrent left lumbar ganglionectomy; *c*, cool room experiment; *c*, quadruple ligation and excision of the fistula.

thema or operation (Fig 5a'). This functional change in the response to stimuli which normally call forth a high degree of vasomotor activity had been similarly seen previously in the cool room experiment in which the abnormal limb did not constrict as well as the normal limb. This abnormal response may be explained by (1) altered distribution of blood volume in the limb, (2) the abnormal blood and venous channels in the functional and structural characteristics of the vessels as a result of long standing effects of the fistula.

A number of preliminary trials with ether anesthesia demonstrated this delayed response of the abnormal leg to be a constant finding. Despite the evidence of good 'collateral' circulation we performed our operative removal of the lumbar sympathetic ganglia (L₂ to and including L₅) with the intervening chain by a transabdominal route. In 4 animals, the excitation was bilateral in one stage so that there might be a control side with which to compare the physiologic response to sympathectomy. In the remaining 3 the procedure was carried out only on the side on which there was a fistula. This would more clearly reveal the results to be expected from clinical application of sympathectomy to a limb having an arteriovenous fistula.

Cutaneous temperatures of the toes and entire limb were obtained after the sympathectomy and these observations were recorded daily thereafter for more than two weeks. Then after a cool room test, the fistulas of 2 animals from both groups were excised after quadruple ligation.

Bilateral sympathectomy—Before sympathectomy the previously normal right leg showed a marked gradient of from 37.0 degrees to 31.5 degrees C whereas after sympathectomy the skin surface of the entire limb was close to 37.0 degrees C, being lowest (35.5 C) at the ankle (Table 1b). This demonstrated a maximal response of the cutaneous vessels to vasomotor denervation. The left limb which had had an arteriovenous fistula in the thigh for 7 months responded in much the same manner except for quantitative differences. As before sympathectomy, the thigh and leg were warmer than those of the

control limb but the foot and toes were 0.5 to 1.5 degrees C cooler than those of the control sympathectomized side. This relationship of toe temperatures therefore continued to be constant, even after sympathectomy indicating the rôle the fistula plays in preventing a normal distal blood flow, regardless of environmental or vasomotor activity.

Following the bilateral sympathectomy the same elevation of cutaneous temperatures of the toes was recorded as was obtained when the animals were under deep ether anesthesia preliminary to both unilateral and bilateral sympathectomy (Fig 5a'). During the subsequent 2 weeks however the temperature of both limbs decreased gradually about 1.0 to 1.5 degrees C as measured between the toes.

When these animals were given the cool room test, that is exposure to an air temperature of 18 degrees C. for 30 minutes, neither limb showed significant evidence of vasoconstrictive ability. In 2 of the animals that had bilateral sympathectomy of 2 weeks duration the fistula was isolated and removed by quadruple ligation and excision. It was immediately noted that the removal of this communication was attended by a slight but significant rise in toe temperature to almost the equal of the control side. This is explained by a redistribution of arterial blood through the distal artery.

Fig. 4. Cutaneous temperature of the toes, in addition to rectal and air temperatures, the operative production of left arteriovenous fistula, *b*, cool room experiment *c*, quadruple ligation and excision of the fistula.

Having demonstrated by arteriograms that these dilated channels did not extend to the foot we could depend with considerable confidence on temperature changes of the toes as being a reliable index of arterial flow.

In order to follow these changes closely cutaneous temperatures of the toes were measured daily following the establishment of an arteriovenous communication in the left femoral vessels. Concurrent recordings were made of the rectal and air temperatures in order to note excessive variations of temperature in the body or in the environment. The control values noted prior to the vascular operation were rather constant (Fig. 4). Immediately after the production of an arteriovenous fistula there was a sharp drop of toe temperatures of the limb on which operation had been performed almost to room temperature (Fig. 4*a*). This was due to (1) vasospasm resulting from manipulation and (2) the distal ischemia due to the blood flow into the low pressure region at the fistula rather than to the tissues beyond. During the next day there was a sharp rise of the temperature of the leg with the fistula of about 2 degrees C., probably representing a decrease of vasospasm that had resulted from the operation. The normal leg and rectal temperatures rose slightly as evidence of a general reaction to the operation. This lasted but 1 to 3 days, and thereafter these temperatures followed the normal levels

(toe = 31.5° C. average rectal = 38.0° C. average). During subsequent days the toe temperature of the limb with the fistula increased but became relatively constant about 10 degrees to 20 degrees C. below the control temperature of the right limb in 7 to 12 days.

In the subsequent period the response of the limbs to an abnormally cool environment was studied (Fig. 4*b*). On several occasions each animal was exposed to air temperature of 18 degrees C. for 30 minutes, and 15 minutes after removal of the animal to a room at about 26 degrees C. the temperature of the toes was recorded. It is significant that the normal side responded most efficiently to alterations of external environment. This greater vasoconstrictive ability of the normal limb made the leg with the fistula seem relatively warmer.

In some of the animals, quadruple ligation and excision of the fistula was performed after 44 months. A rise of toe temperature of the fistulous leg was noted on excision of the communication (Fig. 4*c*). This was probably due to redistribution of arterial blood with a more normal blood flow through the distal capillary beds.

Effects of sympathectomy. After a period of 7 months had been allowed for definite physiologic changes to have taken place, so far as the general and local cardiovascular systems were concerned 7 dogs were selected from the group and repeated preoperative temperature readings were taken (Fig. 5 up to *a*). Prior to a sympathectomy the animals were given ether anesthesia in an effort to simulate the effects of the operation since Herrick and associates and Baldes and associates had showed that the 2 procedures caused an identical increase in blood flow in the femoral artery of the dog. We soon discovered that under light ether anesthesia there was a lag in vasodilatation in the limb with the fistula, the rise in temperature being only about 2.5 degrees C. instead of the 5.5 degrees C. average of the normal side (Fig. 5*a*). This lessened response was shown to be a lag rather than organic inability to respond since under deep ether anesthesia (or lumbar sympathetic ganglionectomy) the temperature of the leg with the fistula continued to rise to a total average of 4.5 to 5.0 degrees C. higher than before anes-

DETERLING ET AL. ARTERIOVENOUS FISTULA

Bush (32) have reported cardiac failure in a period of only a few days or weeks after the development of a traumatic fistula. Fick found some of the vascular alterations irreversible and argued for early operation on patients who have arteriovenous fistula. Harbison has similarly urged early operation after employing sympathectomy to increase the collateral circulation so that frequently associated nerve injuries can be repaired easily. Elkin (9, 10) reported early operation to have been performed frequently on soldiers without even sympathectic block being necessary. However the important effect that sympathectomy exercises on the full development of collateral systems has been emphasized by Mulvihill and Harvey. They concluded that at least the interruption of efferent vasomotor impulses by ganglionectomy imitates the establishment of the collateral circulation and to all appearances in the same manner as it occurs after a time of itself.

The first clinical application of this fundamental principle was reported by Gage (14) in 1933 in the treatment of a mycotic aneurysm of the iliac artery. By paravertebral sympathectic block the circulation in the limb was increased sufficiently to allow ligation of this large vessel with impunity. Subsequently in 1939 (15) he stated that he "had similar and satisfactory results with arterial and arteriovenous aneurysms."

Bird in 1935 was perhaps the first to report the preoperative use of sympathectomy preparatory to the repair of a major peripheral aneurysm. Plotkin in 1939 reported excellent results from lumbar sympathectic ganglionectomy performed in the presence of marked ischemia of the leg 134 hours after excision of a popliteal arteriovenous fistula. In 1940 Waugh treated an arteriovenous fistula in which the collateral circulation was so poor that sympathectomy was done before excision of the fistula. The patient experienced such symptomatic improvement that he temporarily refused further treatment for the fistula. (Subsequently Waugh has had further recourse to sympathectomy as a preparation for obliterative procedures for arteriovenous fistulas.) In 1943 the "Military manual of traumatic surgery" (35) suggested that in cases of arterio-

venous fistula in addition to the usual methods of treatment, sympathectomy "may be of value. Subsequently a War Department "Bulletin on care of battle casualties" (48) noted that while most arteriovenous fistulas do not require emergency treatment, a certain number must have early surgical treatment in the presence of hemorrhage, impending rupture, paralysis from the pressure on the nerves near the aneurysm or threatened gangrene. It suggests that preoperative and postoperative injections of 1 per cent solution of procaine hydrochloride to block the sympathetic ganglia or sympathectomy may be used in vascular cases to improve circulation by removing vasospasm. Recently there have been promising reports by Linton and White, Pugh, Harbison, Kirtley, Mason and Giddings (31), Shumacker and Carter and Freeman in which there was definite evidence of stimulation of collateral circulation in chronic arteriovenous and arterial aneurysms by paravertebral block or sympathectomy. Early operation has been possible and when there was an attendant nerve injury repair of the nerve has been facilitated. Naide has had encouraging results from sympathectic block to supplement anti-toxin and penicillin in gas gangrene infections. This study has shown that while such a series

of sequel to arteriovenous fistula as ischemic gangrene is relatively uncommon there does exist frequently a preoperative and postoperative chronic vascular insufficiency which may be relieved by interruption of the sympathetic vasomotor control. The influence exerted by the earlier investigators in so far as depending on the time factor for the development of collateral circulation is very strong. Elkin (9) in his treatment of 106 patients who had traumatic aneurysms observed in a military hospital has not employed procedures that might be used to stimulate collateral circulation other than intermittent compression before employing obliterative operations. Many competent physicians have gone so far as to declare that attempts to improve circulation in cases of chronic arteriovenous fistula were actually contraindicated.

The results of clinical application of interruption of the sympathetic nerves performed to develop collateral circulation before opera-

olar and capillary beds as a result of removing the arteriovenous communication

Unilateral sympathectomy—As in the preceding experiment concurrent readings were made of both hind limbs rectal and air temperatures (Fig 5) These results represent the type of response one may expect in the clinical application of lumbar sympathectomy to patients having arteriovenous fistula of the leg

The response to ether anesthesia in this series of animals was again identical with that previously described for the animals in other series. Under light anesthesia a lag in the temperature rise was noted in the limb with the fistula compared to the immediate complete response of the control normal limb (Fig 5a) With deep ether anesthesia the temperature continued to rise to a level about 1.0 degree C below that of the normal side (Fig 5a') At this point left lumbar ganglionectomy was performed

After recovery from ether anesthesia, the temperature of the control limb fell to the pre-operative level or slightly lower indicating in some instances a contralateral vasoconstriction This latter phenomenon was only transient however On the sympathectomized side the elevated cutaneous temperature persisted at a level of about 37 degrees C. During the subsequent 2 weeks this significant rise of toe temperature was maintained with only a slight decline to about 36.0 degrees C or an elevation of 3.0 to 4.5 degrees C over that of the normal control side (Fig 5a to b) Thus fact demonstrated conclusively that the vessels distal to the fistula were indeed capable of further vasodilatation even after a period of 7 months in which collateral circulation had developed.

As in the other groups, these animals were given the cool room test there was only a slight fall of about 1.0 degree C. in the temperature of the sympathectomized limb as compared with a decrease of temperature of more than 8 degrees C in the normal limb (Fig 5b) This is clear evidence that an anatomic interruption of the vasomotor nerves had been accomplished by the sympathetic ganglionectomy

Two animals were selected from this group Two weeks after the unilateral sympathec-

tomy the fistula was excised by quadruple ligation and excision. Once again a slight but significant rise of toe temperature was observed indicating increased distal arterial flow after obliteration of the fistula (Fig 5c).

Comment It is evident that our experiments have indicated that the blood flow in a limb may be significantly increased in the presence of a chronic arteriovenous fistula of a major peripheral artery following sympathetic denervation The adequate treatment of arteriovenous fistula depends primarily on the condition of the collateral blood supply when an obliterative procedure is the method of choice Naturally the secondary factors of general condition of the patient, his cardiac status and presence of infection or nerve involvement are important but in the presence of insufficient blood supply little choice remains to the surgeon beyond temporary ven ligation amputation or in certain cases, restorative endoaneurysmorrhaphy In any operative procedure in which the arteries are involved one runs the ever present danger of disastrous vasospasm as a result of the surgical manipulation The present-day safeguards against thrombosis, such as precise aseptic technique improved antibiotic agents and the anticoagulant drugs, heparin and dicoumarol, have made direct repair or ligation of major peripheral arteries a less formidable procedure than in the past century or even during World War I

There is considerable evidence both direct and indirect that the majority of channels composing a collateral system are in existence, even though relatively inactive in the normally functioning part In the dog many investigators have demonstrated by arteriography the ready appearance of supplementary arterial channels when obstruction had occurred in various regions Vvedenski in the hind limb Kolesnikow in the fore limb Andreyev in the head

The demonstration of the great differences in the arterial and arteriovenous bed in the limbs of our animals that had fistulas raises the question whether a surgeon is justified in waiting several months for collateral circulation to develop before closure of a fistula in a patient. Mason (30) and Mason Graham and

DETERLING ET AL. ARTERIOVENOUS FISTULA

ash (32) have reported cardiac failure in a period of only a few days or weeks after the development of a traumatic fistula. Fick around some of the vascular alterations irreversible and argued for early operation on patients who have arteriovenous fistula. Harbison has similarly urged early operation after employing sympathectomy to increase the collateral circulation so that frequently associated nerve injuries can be repaired easily. Elkin (9, 10) reported early operation to have been performed frequently on soldiers without even sympathetic block being necessary. However, the important effect that sympathectomy exercises on the full development of collateral systems has been emphasized by Mulvihill and Harvey. They concluded that 'at least the interruption of efferent vasomotor impulses by ganglionectomy initiates the establishment of the collateral circulation and to all appearances in the same manner as it occurs after a time of itself.'

The first clinical application of this fundamental principle was reported by Gage (14) in 1933 in the treatment of a mycotic aneurysm of the iliac artery. A NEW OPERATIVE TREATMENT FOR ELEPHANTIASIS

EDGAR J POTH M.D. Ph.D., F.A.C.S., SAM R. BARNES, M.D., and
GRIFF T ROSS M.D. Galveston, Texas

WE shall not consider the various etiological factors of elephantiasis (Matas 1913) but shall concern ourselves with the late stage of persistent irreversible edema with fibrosis of the subcutaneous tissues and derma in those instances or recurrent erysipieloid infections due to lymphatic obstruction.

Homans (1928) Homans and Zollinger (1929) Homans Drinker and Field (1934) Reichert (1926 1927 1930) and many others have treated this subject experimentally and clinically. It has been concluded that the most satisfactory treatment of this malady is the complete removal of the lymphatic bearing tissues especially of the legs and occasionally of the thighs. Of the various procedures used to accomplish the removal of these tissues the Kondoleon (1912) operation of excising segments of skin and the underlying fibrous connective tissues extending down to the

muscles or by the undercutting of thin skin flaps and excising the lymphatic bearing subcutaneous tissues (Sistrunk 1927) have been used most extensively and are considered as giving the best results. These procedures are multiple time-consuming operations requiring long hospitalization. The condition frequently recurs or is not relieved. In a true elephantiasis with progressive fibromatosis as defined by Matas, the lymphatics of the derma are involved in addition to those of the subcutaneous tissue.

This paper describes a single operation for the removal of the lymphoid bearing tissues. The procedure is simply the excision of all tissues down to the sheaths of the muscles of the thigh and leg excepting a narrow strip covering the tibia anteriorly and then grafting the denuded surface with thick split grafts.

Alternate procedures are illustrated in Figures 1 and 2.

CASE REPORT

C. M., No. 275574, white male aged 34 years was first observed to have an enlarged left leg at the age of 2 months which was subsequently diagnosed as

From the Department of Surgery, University of Texas, Medical Branch, Galveston, Texas.

Presented at the forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1940.

Fig. One stage operation for elephantiasis. A, The incisions are outlined so as to preserve full thickness of tissue over the tibia. B, If the condition of the skin is satisfactory, thick split grafts are cut before the tissues are dissected from the operative field. Grafts are cut from the entire circumference except for the narrow strip over the

tibia. C and D show the remaining derma and subcutaneous tissues being excised down to muscle with preservation of a strip of tissues over the tibia. E and F illustrate the situation after grafting with split skin grafts. Note—If indicated, the subcutaneous tissue over the tibia could be excised after healing has occurred.

Fig. 2. An alternate two stage operative procedure. Illustrations A, B and C show the removal of the subcutaneous tissue from the area covering the tibia. Illustrations D, E, F and G show the completion of the operation after the flap over the tibia has healed and a new blood supply has been established.

Milroy's disease. The enlargement and edema have increased progressively with recurrent attacks of erysipeloid infection pain, and fever. A Kondoleon operation in 1935 gave temporary improvement. Daily baths followed by sponging with 1:4000 cephalorin solution as a preoperative measure succeeded in clearing the left leg of numerous small furuncles. The skin of the leg was thickened but still retained some elasticity. It was decided to cut split grafts from this surface before excising the remaining skin and subcutaneous connective tissues down to the muscle sheath, and to use these grafts to cover the dissected area. A strip of skin and subcutaneous tissue was left to cover the tibia anteriorly (Figure 1). If the local skin is not suitable for transplantation other donor sites should be selected. It is questionable whether the local skin should ever be used because the lymphatic vessels of the derma are involved in elephantiasis.

The skin grafts were dressed with glycerine con-

taining zephiran in 1:1000 concentration (Poth 1945). Postoperative course was uncomplicated. Dressings were first changed on the twelfth post operative day. The appearance 3 weeks and 3 months postoperatively is shown in Figures 5 and 6.

The patient has been relieved of his disability and is working as a laborer. The edema of the foot has become progressively less. A year has passed without recurrence of infection. While no supportive dressing has been worn by this patient, it is desirable to use an elastic bandage or stocking for a year to 18 months following operation.

DISCUSSION

Many patients with elephantiasis are incapacitated by the enlarged limb. The operation outlined here causes considerable disfigurement and should not be undertaken early.

Fig. 3. The tissue excised weighed 270 grams. A, left, shows the rolled specimen from which split grafts were cut. B, shows the deep surface.

INDICATIONS FOR PORTACAVAL ANASTOMOSIS— ANALYSIS OF CASES

ARTHUR H. BLAKEMORE, M.D. New York, New York

✓
THE first anastomosis to join the portal and caval system of veins was made in 1877 by Von Eck, a Russian physiologist. His operation upon dogs, anastomosing the portal vein to the vena cava, side-to-side, became widely known as the Eck fistula. Surgeons early recognized the rationale of establishing portacaval shunts for the relief of portal hypertension and over the years from 1903 to 1914 occasional case reports appeared in the literature (3, 4).

That severe portal hypertension may cause gastrointestinal hemorrhage has long been known, but the rôle of portal hypertension in conjunction with deranged blood proteins in association with ascites is more recently better understood. In an experience covering the completion of 23 portacaval anastomoses with follow-up observations, some data having bearing upon the selection of cases for the operation have been accumulated. Since the portacaval shunt affords a rational approach to the control or amelioration of hemorrhage due to portal hypertension, I will first discuss indications for its use for this purpose.

Patients with congestive splenomegaly exhibiting Banti's syndrome who give a history of one or more episodes of gastrointestinal bleeding but whose liver function tests are essentially normal may be classified as cases of portal hypertension due to extrahepatic portal block. Such patients are candidates for a portacaval shunt. In the majority of these cases the portal block is due to cavernomatous transformation or atresia of the portal vein. Since it is not feasible to anastomose the portal vein to the vena cava in the above type of case, the splenic vein to renal vein becomes the portacaval anastomosis of choice in this group. It is the surgeon's responsibility in dealing

with such cases to be prepared to perform a splenorenal anastomosis before proceeding with a splenectomy. Venous pressure readings, properly taken at operation, are an indispensable aid in localizing the site of obstruction in the portal radicals. It is now an established fact that splenectomy alone for congestive splenomegaly will cure only that relatively small group of cases of thrombosis of the splenic vein in which the site of obstruction is distal to the junction of the coronary vein. In such cases venous pressure readings taken from known branches of the superior mesenteric and coronary veins are found to be normal.

THE RÔLE OF THE PORTACAVAL SHUNT IN PORTAL CIRRHOSIS OF THE LIVER

The very fact that hemorrhage or ascites or both can occur in cirrhosis cases purely on the basis of extremely depressed liver function places a great responsibility upon the surgeon in the selection of cases for the portacaval shunt operation. I will cite cases to illustrate this point.

The first case was that of the wife of a physician whose first complaint was uterine bleeding. A dilatation and curettage revealed no cause for the bleeding and finally during the performance of a hysterectomy cirrhosis of the liver was discovered. Subsequent liver function and chemistry studies revealed a badly decompensated liver. The prothrombin time was markedly elevated. The patient's general condition progressively deteriorated. Some 3 months later she experienced her first episode of gastrointestinal hemorrhage. Over a period of 3 months the patient was continuously confined in the hospital suffering repeated hematemeses occurring at monthly intervals. Finally the patient was placed upon a high protein, high carbohydrate diet with large doses of vitamin B complex. Gradually her appetite and strength improved. Some 4 months later following a 6 weeks vacation in Florida, the patient was admitted to the Presbyterian Hospital for study. The liver was found to be rather hard and enlarged. There was no ascites present. Esophagograms revealed small esophageal varices. The blood proteins

INDICATIONS FOR PORTACAVAL ANASTOMOSIS— ANALYSIS OF CASES

ARTHUR H. BLAKEMORE, M.D. New York, New York

THE first anastomosis to join the portal and caval system of veins was made in 1877 by Von Eck, a Russian physiologist. His operation upon dogs, anastomosing the portal vein to the vena cava, side-to-side, became widely known as the Eck fistula. Surgeons early recognized the rationale of establishing portacaval shunts for the relief of portal hypertension and over the years from 1903 to 1914 occasional case reports appeared in the literature (3, 4).

That severe portal hypertension may cause gastrointestinal hemorrhage has long been known but the rôle of portal hypertension in conjunction with deranged blood proteins in association with ascites is more recently better understood. In an experience covering the completion of 23 portacaval anastomoses with follow-up observations some data having bearing upon the selection of cases for operation have been accumulated. Since the portacaval shunt affords a rational approach to the control or amelioration of hemorrhage due to portal hypertension I will first discuss indications for its use for this purpose.

Patients with congestive splenomegaly exhibiting Banti's syndrome who give a history of one or more episodes of gastrointestinal bleeding but whose liver function tests are essentially normal may be classified as cases of portal hypertension due to extrahepatic portal block. Such patients are candidates for a portacaval shunt. In the majority of these cases the portal block is due to cavernomatous transformation or atresia of the portal vein. Since it is not feasible to anastomose the portal vein to the vena cava in the above type of case, the splenic vein to renal vein becomes the portacaval anastomosis of choice in this group. It is the surgeon's responsibility in dealing

with such cases to be prepared to perform a splenorenal anastomosis before proceeding with a splenectomy. Venous pressure readings properly taken at operation, are an indispensable aid in localizing the site of obstruction in the portal radicals. It is now an established fact that splenectomy alone for congestive splenomegaly will cure only that relatively small group of cases of thrombosis of the splenic vein in which the site of obstruction is distal to the junction of the coronary vein. In such cases venous pressure readings taken from known branches of the superior mesenteric and coronary veins are found to be normal.

THE RÔLE OF THE PORTACAVAL SHUNT IN PORTAL CIRRHOSIS OF THE LIVER

The very fact that hemorrhage or ascites or both can occur in cirrhosis cases purely on the basis of extremely depressed liver function places a great responsibility upon the surgeon in the selection of cases for the portacaval shunt operation. I will cite cases to illustrate this point.

The first case was that of the wife of a physician whose first complaint was uterine bleeding. A dilatation and curettage revealed no cause for the bleeding and finally during the performance of a hysterectomy cirrhosis of the liver was discovered. Subsequent liver function and chemistry studies revealed a badly decompensated liver. The prothrombin time was markedly elevated. The patient a general condition progressively deteriorated. Some 3 months later she experienced her first episode of gastrointestinal hemorrhage. Over a period of 5 months the patient was continuously confined in the hospital suffering repeated hematemeses occurring at monthly intervals. Finally the patient was placed upon a high protein high carbohydrate diet with large doses of vitamin B complex. Gradually her appetite and strength improved. Some 4 months later following a 6 weeks vacation in Florida the patient was admitted to the Presbyterian Hospital for study. The liver was found to be rather hard and enlarged. There was no ascites present. Esophagograms revealed small esophageal varices. The blood proteins

BLAKEMORE INDICATIONS FOR PORTACAVAL ANASTOMOSIS

marized and clarified by classifying cases of cirrhosis in three groups as follows: Group I, cases in which ascites or a tendency to hemorrhage is based on the inability of the damaged liver to form albumin or prothrombin in adequate amounts. Portacaval anastomosis is not indicated in this group. Group II cases of cirrhosis in which the liver function is adequate to furnish the required amount of albumin and prothrombin but as a result of fibrotic contraction and periportal fibrosis a severe degree of portal hypertension has supervened. Wasting ascites and severe hemorrhage can be controlled in this group only by the portacaval shunt. Group III cases of cirrhosis having varying degrees of depressed liver function plus evidence of considerable elevation of the portal pressure. Such cases are candidates for the portacaval shunt operation but the question is when. It is our present policy to study the individual case with exceeding care when ever possible over a sufficient period of time to become thoroughly familiar with the behavior of the liver before bringing the case to operation. This is usually possible even in patients who have been subject to recurring hemorrhages. The idea is to improve liver function to its maximum employing a comprehensive liver regimen energetically applied for as long a period as necessary.

DISCUSSION

The portacaval shunt operation is indicated and affords a chance of ultimate survival for cases of Banti's syndrome with extrahepatic portal block cases in which there is hypertension in the coronary or portal veins.

The portacaval shunt has an equally important rôle in the treatment of portal hypertension due to cirrhosis of the liver. But, its application must be decided on the basis of portal hypertension being the primary cause of hemorrhage or ascites in the individual case.

ANALYSIS OF CASES

The portacaval shunt operation has been completed in 23 cases. There have been 4 postoperative deaths.

Hemorrhage from a sizable collateral vessel discovered at the conclusion of an anastomosis of the portal vein to vena cava accounted for

death in a case of cirrhosis of the liver. One cirrhosis patient died of cholemia 4 days following the establishment of a splenorenal shunt. Another cirrhotic patient died also of liver failure 6 days following the establishment of a portal vein to vena cava anastomosis. The fourth death resulted from mesenteric thrombosis occurring on the 14th day following a splenorenal anastomosis. The first death was the result of technical error. Death from liver failure in the 2 cirrhotic patients involves essentially errors in judgment in the selection of cases. Whereas mesenteric thrombosis is in the lap of the gods!

Patients have been explored in whom it was not feasible to accomplish a shunt operation. The majority of these patients had been subjected to a previous splenectomy. Of the 23 cases in which portacaval shunts were completed there were 15 patients who had anastomosis of the splenic vein to the renal vein following splenectomy and left nephrectomy. One of these patients had had a splenectomy at a previous operation. In one other post splenectomy bleeder it was possible to anastomose the stump of the splenic vein to the vena cava end to-side, by suture.

Anastomosis of the portal vein to the vena cava end to-side, was carried out seven times. A 12 millimeter vitallium tube was used four times (1) a 10 millimeter once and suture anastomosis once.

Seventeen of the 19 patients surviving operation have a follow up exceeding 6 months. Two deaths have occurred: one a child having portal cirrhosis, died some 2 years 4 months postoperatively of uremia due to polycystic disease of the kidney; the second case a man with bad portal cirrhosis, died 1 year following operation of cholemia. A necropsy examination was made in each case. In the child the splenorenal shunt had become occluded. This outcome was not unexpected because at operation in this, our first case there was considerable angulation of the splenic vein over the funnel edge of the vitallium tube. The splenorenal anastomosis in the second case was found to be patent.

Five additional patients with bad cirrhosis of the liver have been followed (2 cases 2

Fig 1 Case 53689. a, left, Infrared photograph. Note distention of abdomen with ascites, umbilical hernia and the presence of superficial collateral veins. b, Same patient 5 months after the establishment of a splenorenal shunt. The ascites has completely disappeared.

years each 3 cases $1\frac{1}{2}$ years each) All for the most part, have done satisfactorily considering their preoperative status. All of the patients are active and 4 of the 5 are working. There was delay in disappearance of ascites following operation in 1 a minor bleeding episode in another.

I should like to discuss in more detail a sixth case, a patient with extrahepatic portal vein obstruction and biliary cirrhosis who has been followed now 2 years since the establishment of a splenorenal shunt.

CASE 53689. The question of performing a portacaval shunt procedure on this 46 year old man arose during an admission for hematemesis in November 1944. This was his 10th admission to the Presbyterian Hospital over a 7 year period.

His initial troubles began with an impacted gall stone causing cicatricial stenosis of the distal common duct and fibrotic pancreatitis. The latter caused partial obstruction of the duodenum and finally obstruction of the portal vein. As corrective measures, a gastroenterostomy and a cholecysticjunostomy were performed. Some 5 years later because of recurring attacks of jaundice cholangitis, and a persistently high alkaline phosphatase, an

operation connecting the proximal end of the common duct to the pylorus using a vitallium tube was performed. In spite of this procedure over the next 3 years this patient's health continued to deteriorate. There was progressive loss of strength appetite, and weight. The episodes of cholangitis recurred in spite of long periods of therapy with sulfadiazine. The liver remained large with laboratory evidence of progressive cirrhosis. The spleen became more and more enlarged *pari passu* with the development of prominent superficial veins over the abdomen. Finally esophagograms revealed the presence of varices. Ascites supervened. Over an 8 month period prior to this admission the patient suffered five episodes of severe gastrointestinal hemorrhage.

On November 30, 1944, a splenorenal portacaval shunt employing a vein graft with two 5 millimeter vitallium tubes was carried out. Following the above procedure there was a reduction in size of the superficial abdominal veins. The ascites, which had been present for some 8 months before operation, gradually disappeared. Over the first 10½ months following the establishment of the portacaval shunt the patient gained 22 pounds. His appetite and digestion were excellent. He was working daily until October 12, 1945 when he caught cold. Following a severe coughing attack the patient had abdominal pain and 2 days later the patient passed 2 or 3 tar stools. This episode cleared promptly however.

BLAKEMORE INDICATIONS FOR PORTACAVAL ANASTOMOSIS

with a rapid return of strength and appetite. Some 3 months later in January 1946 the patient began to have gas on the stomach with upper abdominal pain. The pain was relieved temporarily by eating or the ingestion of alkalis. One month later (February 1946) the patient again passed a few tarry stools. He was hospitalized for a short while during which he recovered his strength nicely but continued upon discharge to suffer daily from intermittent abdominal pain. A month later (March 25 1946) the patient was admitted for his third episode of tarry stools since the portacaval shunt operation. Because of the persistence of intermittent attacks of food intolerance pain favorably affected by the ingestion of food or alkali the presence of a marginal ulcer was considered but not proved by x ray. Nevertheless this patient's stools did not become guaiac negative until after the administration of amphotel therapy during which time the attacks of abdominal pain entirely disappeared. The patient has continued free of digestive symptoms or pain now some 6 months during which there has been no recurrence of bleeding from the gastrointestinal tract.

See Figure 1 infrared photographs a before operation b 5 months after operation.

This patient has had three episodes of gastrointestinal bleeding since operation. Three possible causal factors may be discussed in explaining the recurrence of bleeding.

- 1 Occlusion of the anastomosis a femoral vein graft mounting a 5 millimeter vitalium tube on either end was employed to bridge the splenic and renal veins in this case—a technique which combined what we now consider 2 objectionable features namely the employment of a vein graft and the use of vitalium tubes of a diameter undesirably small. On the other hand there is an extremely good argument against occlusion of the anastomosis as being the cause of the recurrence of bleeding in this case.

- 2 Hemorrhage from a marginal ulcer at an old gastroenterostomy site. Against this as a source of bleeding was the failure to demonstrate a marginal ulcer in this case by x ray. It is of extreme interest, however, that the first bleeding episode to occur following the establishment of the portacaval shunt manifested itself in tarry stools 2 days after the onset of epigastric pain. The patient stated that at the time he had a coryza and a productive cough—the pain following a coughing episode Three months later the epigastric pain recurred accompanied by the eructation of gas. The ingestion of food would relieve the pain

temporarily. These new symptoms persisted and during the next 3 months occurred the second and third bleeding episodes. The persistence of guaiac positive stools and abdominal pain was protracted until the institution of amphotel therapy following which the pain ceased and the stools rapidly became guaiac negative. The patient's digestion and appetite improved steadily and now 6 months later the patient has gained 18 pounds and his stools remain guaiac negative.

- 3 A third possible explanation for the bleeding in this case is a logical one, namely the rather small (5 mm.) vitalium tubes employed may not handle a volume of blood adequate to lower pressure in the portal radicals sufficiently under conditions of sudden strain or possibly in the presence of mucosal ulceration. One look at the size of the collateral veins over this man's abdomen lends distinct credence to this explanation.

Though a splenorenal shunt be not adequate in size to afford total protection against the occurrence of bleeding that does not mean it will not do yeoman service in lessening the number and severity of attacks—a logical explanation of the clinical behavior in this case.

Our experimental evidence and clinical experience indicate that if a blood vessel anastomosis remains patent up to 60 days following operation it is extremely likely to remain open permanently. Here is a man who for 8 months prior to operation had ascites requiring paracentesis. During this period there were 5 episodes of severe gastrointestinal hemorrhage including hematemesis. For a month prior to operation the patient's condition was extremely precarious due to persistent gastrointestinal bleeding. A splenorenal shunt was established at this point. Following operation there was marked clinical improvement. The ascites disappeared and there was a gradual gain in weight of 22 pounds.

It is logical to conclude that the patency of the anastomosis accounted for the disappearance of ascites in this case. The presence of persistent ascites for 8 months prior to operation had been conceded by all to be on the basis of portal vein compression due to a fibrosing pancreatitis. Whereas the patient did have biliary cirrhosis there was never at

NOTE. All cases of cirrhosis of the liver.

any time evidence of decompensation of the liver. Furthermore up until the time of disappearance of the ascites following the establishment of the portacaval shunt, the patient was not on a liver dietary regimen. In view of the above fact, if the bleeding episode which occurred 10½ months after operation in this man had been due to a sudden closure of the splenorenal shunt one would have expected a prompt return of the ascites. In fact, in a very recent case in which thrombotic occlusion did take place the prompt occurrence of ascites antedated the appearance of esophageal bleeding by 2 weeks.

It seems reasonable that this man's splenorenal shunt may be open but not of a size adequate to shunt enough blood to afford complete protection against hemorrhage. After

all, he has had only three episodes of gastrointestinal hemorrhage in a 24 months post-operative period compared to 5 attacks over an 8 months period before operation. He is free of ascites, and working.

We do not have, as yet, enough follow-up data on portal pressures before and after opening portacaval shunts to predicate what pressure level will afford absolute protection against hemorrhage. However we do have data upon portal pressures to indicate that the splenic vein may not always be of adequate size to afford a shunt sufficiently large to protect against episodes of hemorrhage. As a possible corollary to the importance of the size of the shunt our follow-up has not so far been complicated by hemorrhage in those cases in which direct anastomoses of the portal

terminal illness from liver failure. Whereas it seems likely that a low blood prothrombin level may have contributed to the initiation of hemorrhage, it must be remembered that this patient still had a portal pressure of 240 millimeters of water following opening of the shunt. Before operation the portal pressure was 400 millimeters of water—the highest pressure we have yet recorded on a case of cirrhosis. Though this patient's ascites cleared following operation his jaundice persisted. His terminal illness was ushered in by a high fever from what appeared to be an upper respiratory infection. It is only fair to state at this point however that following the establishment of a splenorenal shunt, this man's appetite strength and weight improved. He was able to return for part time work to his job as a barber.

The above case proves that a splenorenal shunt, though patent, may not be of a size adequate to shunt an amount of blood sufficient under all conditions to afford absolute protection against future hemorrhage. Three additional cases over a 2 year follow up period have shown such marked overall clinical improvement following the portacaval shunt operation as to justify including them in the above classification.

One of the cases has already been discussed in detail. One case a girl of 15 years having Banti's syndrome with extrahepatic portal block was found to have a portal pressure of 310 millimeters of water. Following the opening of a splenorenal anastomosis the portal pressure receded to 190 millimeters of water. This patient gained strength and weight following operation but over a 2½ year (30 month) follow-up period she has had three episodes of gastrointestinal bleeding. Two of these hemorrhages were comparatively trivial to the attacks which came regularly at 6 month intervals before operation.

A third case a cirrhotic who gave a long past history of hematemesis, was operated upon following a month's seizure of hemorrhage during which the stools failed to become guaiac negative. Following the establishment of a portacaval shunt, this man's general condition improved markedly. His jaundice gradually improved as well as his liver

function tests. A few months after operation, the patient returned to his job and has been working ever since. Over a 2 year follow-up period this man has had one comparatively minor bleeding episode consisting of 2 or 3 tarry stools.

Finally there are 3 cases in which the evidence points to closure of the portacaval anastomoses. All 3 cases have Banti's syndrome with a past history of frequent episodes of gastrointestinal bleeding including hematemesis. In 1 case that of a 15 year old girl, who 4 years previously had had a splenectomy an anastomosis was effected by suture of the stump of the splenic vein to one branch of the left renal vein. To the other branch of the renal vein (following nephrectomy) the proximal stump of the inferior mesenteric vein was anastomosed employing a 5 millimeter vitallium tube. Thrombotic occlusion of the anastomoses was heralded by the sudden appearance of ascites on the seventh postoperative day. Some 2 weeks later the patient had an attack of hematemesis. The bifurcated renal branches were rather small in this case and in retrospect it would possibly have been better judgment to have been satisfied with one anastomosis.

The second case was that of an 8 year old boy who one year previously had had a splenectomy. The boy had Banti's syndrome complicated by bronchiectasis. During the year following splenectomy the boy suffered 5 episodes of severe gastrointestinal hemorrhage including hematemesis. The proximal stump of the splenic vein was anastomosed to the vena cava by suture end-to-side. During a year following this procedure, as presumptive evidence of closure of the anastomosis, the hemorrhages have recurred with equal frequency and severity.

Finally in a child 3 years of age an end-to-end suture of the splenic vein to the renal vein has failed to lessen the tendency to hemorrhage over a year's follow up period.

SUMMARY

In presenting the rationale of the portacaval shunt for the relief of portal hypertension, special stress is placed upon the selection of cases.

BRANTIGAN ANOMALIES OF PULMONARY VEINS

The procedure is presented as the one hope of relief for those cases with Banti's syndrome who have essentially normal livers but present the problem of control of gastrointestinal hemorrhage.

The importance of exercising extreme care and judgment in the selection of cases of cirrhosis for operation and the reasons thereof are discussed.

An analysis of 23 cases having portacaval anastomosis was presented

ANOMALIES OF THE PULMONARY VEINS

Their Surgical Significance

O C BRANTIGAN M.D. F.A.C.S., Baltimore, Maryland

THE reports of anomalies of the pulmonary veins are appearing more frequently in the medical literature. In the past all descriptions and case reports have come from autopsy material or from studies made in the anatomical laboratory. This article will describe and discuss anomalies of the pulmonary veins found at the time surgical operations were being performed upon the lungs.

Brody made a review of the literature and in 1942 presented an excellent discussion of the subject. The final study included 106 patients. Since 1942 seven different authors have reported 14 additional cases (3, 4, 7, 8, 10, 11, 12). Brody classified the anomalous venous drainage from the lungs as (1) total drainage into the right atrium or its tributaries, 36 per cent, and (2) incomplete drainage into the right atrium or its tributaries, 64 per cent. When the venous drainage from the lungs into the right atrium or its tributaries is incomplete the most common site for drainage in order of frequency is the superior vena cava, right atrium and the left innominate vein. The right pulmonary vein is anomalous in its drainage twice as frequently as the left.

Anomalous pulmonary veins have been described as draining into the following: superior vena cava, right atrium, left innominate vein, coronary sinus, inferior vena cava, azygos vein, left subclavian vein, portal vein and persistent left superior vena cava.

It has been suggested that if less than 50 per cent of the pulmonary blood is abnormally shunted into the major venous system or into the right side of the heart, the patient is unlikely to develop cardiac decompensation. Such an assumption is based upon a normal heart. Hughes and Rumore were the first to give actual figures that might indicate the quantity of pulmonary blood that flows abnormally into the major venous system from an anomalous pulmonary vein. Both of the patients they described died of cardiac failure and both had rheumatic heart disease. By comparison of the cross-sectional area of anomalous veins with the cross-sectional area of the normal pulmonary veins they calculated that in one patient 26 per cent and in another 20 per cent of the pulmonary blood was shunted into the major venous system. It is difficult to calculate the effects of this additional effort upon the already injured heart. Conant and Kurland described a patient who tolerated extensive tuberculosis in the left lung but died rapidly when the right lung became infected. At autopsy it was found that

terminal illness from liver failure. Whereas it seems likely that a low blood prothrombin level may have contributed to the initiation of hemorrhage it must be remembered that this patient still had a portal pressure of 240 millimeters of water following opening of the shunt. ANOMALIES OF THE PULMONARY VEINS

Their Surgical Significance

O. C. BRANTIGAN, M.D., F.A.C.S. Baltimore, Maryland

THE reports of anomalies of the pulmonary veins are appearing more frequently in the medical literature. In the past all descriptions and case reports have come from autopsy material or from studies made in the anatomic laboratory. This article will describe and discuss anomalies of the pulmonary veins found at the time surgical operations were being performed upon the lungs.

Brody made a review of the literature and in 1942 presented an excellent discussion of the subject. The final study included 106 patients. Since 1942 seven different authors have reported 14 additional cases (3, 4, 7, 8, 10, 11, 12). Brody classified the anomalous venous drainage from the lungs as (1) total drainage into the right atrium or its tributaries, 36 per cent, and (2) incomplete drainage into the right atrium or its tributaries, 64 per cent. When the venous drainage from the lungs into the right atrium or its tributaries is incomplete, the most common site for drainage in order of frequency is the superior vena cava, right atrium and the left innominate vein. The right pulmonary vein is anomalous in its drainage twice as frequently as the left.

Anomalous pulmonary veins have been described as draining into the following superior vena cava, right atrium, left innominate vein, coronary sinus, inferior vena cava, azygos vein, left subclavian vein, portal vein and persistent left superior vena cava.

It has been suggested that if less than 50 per cent of the pulmonary blood is abnormally shunted into the major venous system or into the right side of the heart, the patient is unlikely to develop cardiac decompensation. Such an assumption is based upon a normal heart. Hughes and Rumore were the first to give actual figures that might indicate the quantity of pulmonary blood that flows abnormally into the major venous system from an anomalous pulmonary vein. Both of the patients they described died of cardiac failure and both had rheumatic heart disease. By comparison of the cross-sectional area of anomalous veins with the cross-sectional area of the normal pulmonary veins they calculated that in one patient 26 per cent and in another 20 per cent of the pulmonary blood was shunted into the major venous system. It is difficult to calculate the effects of this additional effort upon the already injured heart. Conant and Kurland described a patient who tolerated extensive tuberculosis in the left lung but died rapidly when the right lung became infected. At autopsy it was found that

Fig. A diagrammatic conception of the primitive venous system viewed from the dorsal aspect. The primitive pulmonary vein enters the dorsal aspect of the sinus venosus. This conception was accepted by the early embryologists.

the blood from the left lung drained anomalously and completely into the left innominate vein. Disease of the nonfunctioning lung caused little embarrassment to the patient, but disease of the functioning lung was rapidly fatal. Thus, the physiologic effect of pulmonary blood shunted into the major venous system will be influenced by disease in the functioning lung or by disease of the heart.

The seemingly wide and unrelated variations that occur in pulmonary venous anomalies have been studied from the embryologic point of view in an endeavor to simplify and correlate the anomalies encountered. Brown reviewed the research that had been done on the development of the pulmonary veins and wrote it is evident that (1) The anlage of the vein and its connections with sinus venosus has not been described in detail and (2) the method by which the vein changes its orifice in the center of the sinus venosus for one in

that position of the sinus which lies to the left of the left sinus valve has not been considered. In addition the general relation which the pulmonary venous system bears to the systemic has been entirely neglected in the study of the embryology of the vein." In the 4.5 millimeter cat embryo he reported "At this stage the pulmonary vein exists as a single vessel having two main vascular connections, (1) ventrally a single rounded orifice in the sinus venosus (Fig. 1) and (2) dorsally a connection with that portion of the splanchnic plexus which is pushed forward by the growing pulmonary anlage which it joins at the ventral pole of the lung bud. Thus, the pulmonary venous plexus through the splanchnic venous plexus is connected with the primitive major venous system by the way of both the precardinal and postcardinal veins. In the 6.5 to 7 millimeter embryo he further related "The sinus venosus with the exception of the openings of the cornua has been incorporated into the auricle. The right valve of the sinus is very prominent and is continued into the septum spurium which has shifted to the left and fused with the septum superius. The left valve of the sinus has likewise shifted to the left and its cephalic extremity on the dorsal wall of the auricle has fused with the dorsal caudal portion of the septum superius. As a result of the latter shift the orifice of the pulmonary vein has preceded the left valve of the sinus, passed under the septum superius and now empties into the left auricle having both septum superius and left valve of the sinus or in other words, the interauricular septum on the right. This view is no longer considered to be true in human development. It is thought that the venous plexus covering the primitive lung bud is probably a development from the splanchnic venous plexus (Fig. 2). The pulmonary venous plexus is gathered together into a common pulmonary vein that joins directly and definitively with the left auricle (6.16). Patten in describing human embryology said "Phylogenetically the lungs are relatively new structures. It is not surprising, therefore, that we find the pulmonary veins arising independently and not by the conversion of old vascular channels. They originate as vessels which drain the various branches of

BRANTIGAN ANOMALIES OF PULMONARY VEINS

Fig. 3. A lateral view diagrammatically representing the primitive venous system and the lung bud and its venous plexus. The primitive pulmonary plexus is an outgrowth from the primitive splanchnic venous plexus. The primitive splanchnic venous plexus communicates with the pre-cardinal and postcardinal veins. The pulmonary vein arises from the primitive pulmonary venous plexus will join directly and definitively with the left atrium. This conception of development for the most part is accepted by contemporary embryologists.

the lung bud and converge into a common trunk entering the left atrium dorsally. In the growth of the heart this trunk vessel is gradually absorbed into the atrial wall until usually 4 of its original branches come to open into the left atrium as the pulmonary veins of the adult. Less than the usual amount of resorption of the primitive common pulmonary vein not infrequently results in the pulmonary veins from the right and the left lungs entering the left atrium as single instead of the usual paired vessels (Fig. 4). In continuation of the discussion Patten made the statement "Occasionally startling anomalous connections of the pulmonary veins are seen such as

Fig. 5. With the exception of the right and left atria, the diagram presents the normal adult structures arising from the primitive venous system. It is viewed from the posterior aspect. If there is a left superior vena cava it is the result of a persistence of the normal remains of the old pre-cardinal vein. If the pulmonary blood is small coronary sinus is the normal remains of the old pre-cardinal vein on the left side. If the pulmonary blood is drained abnormally into the right atrium or its tributaries it will drain into one of the structures indicated on this diagram.

the entrance of one of them into the superior vena cava the left innominate or the azygos. Such conditions are explicable only on the basis of exceedingly early embryonic stages in which the developing foregut trachea and lung buds are supplied by a common plexus of small channels which thread in all directions through the loose mesenchyme and communicate with the primitive cardinal veins freely in many places (Fig. 2). With the enlargement of certain channels in the primordial vascular bed to form pulmonary veins leading to the left atrium the primitive connections with the cardinal veins ordinarily disappear. The unusually strong development of some of these early channels and its retention by the adult derivative of the particular part of the cardinal system involved is behind the occurrence of these abnormal pulmonary connections."

The primitive venous system consisting of the cardinal veins and sinus venosus give rise

Fig. 4. The method of development of an abnormal number of pulmonary veins entering the left atrium is indicated by the diagrams A to G. The dorsal aspect is presented. The primitive pulmonary vein enters the left atrium as a single venous trunk. The primitive single venous trunk is divided into right and a left pulmonary vein, A. The right and left pulmonary veins are divided into two veins, B. There is resorption of the venous trunks into the wall of the left atrium until in the normal adult atrium four pulmonary veins open separately into the posterior aspect of the atrium, C. If the right pulmonary vein divides into three branches, D one for each lobe, close to the atrium they will be resorbed into the atrial wall, thus giving rise to three separate openings on the right side E. If the left pulmonary vein divides into two branches at a greater than normal distance from the atrial wall F they will not be taken up into the atrium and thus only one orifice will open into the atrium on the left, G.

in the adult to the right and left innominate veins, the coronary sinus, the azygos vein, the superior vena cava, the portion of the inferior vena cava adjacent to the atrium, a part of the right atrium and a portion of the portal vein adjacent to the liver. Abnormalities in the persistence of the cardinal veins may give rise in the adult to abnormal azygos veins and to a left superior vena cava (13, 14). When there is anomalous drainage of blood from the lungs, according to all past reports, it has drained into one of the structures above named. Abnormal sites of drainage of pulmonary blood at first glance seem unpredictable but actually they are rather normal from the embryologic point of view. This blood will always drain into some structure originating from the primitive venous system (Fig. 3).

If the early pulmonary veins once drained into the sinus venosus an abnormal shift of its final drainage point could easily account for an abnormal pulmonary drainage into any of the structures originating from the primitive venous system and especially the emptying of pulmonary veins into the right atrium.

Should the pulmonary veins originate from the splanchnic venous plexus (Fig. 2) and then drain first and definitively into the left atrium, certain early connections of the splanchnic venous plexus with the cardinal venous system may persist and thus account for the anomalous drainage of pulmonary blood into any part of the major venous system originating from the primitive venous system. If there is failure of junction of the early pulmonary vein with the left atrium then all blood from the lungs must find an anomalous pathway for drainage. Thus, all anomalies that have been described can be accounted for whether one accepts the old or the new embryologic theory of pulmonary vein development (Fig. 1, 2, 3 and 4).

Embryologists seem to agree upon the essential method of development of multiple openings of the pulmonary vein into the left atrium. The method is described adequately in the quotation from Patten. The various anomalous openings and their method of development have been indicated by the diagrams in Figure 4.

BRANTIGAN ANOMALIES OF PULMONARY VEINS

In the last 3 years pulmonary venous anomalies have been recognized by the author at the operating table. While undergoing pneumonectomy 3 patients were found to have only one pulmonary vein on the left side. Thus, to remove the left lung only one pulmonary vein was ligated as it entered the pericardium. During pneumonectomy 2 other patients presented 3 pulmonary veins on the right side, or an individual vein for each lobe of the lung on the right side. Upon removal of the lung in these 2 patients 3 veins were ligated as they entered the pericardium. In 1 patient where the right lung was removed for tuberculosis the pulmonary vein from the upper part of the right lung drained into the inferior part of the superior vena cava. The pulmonary vein from the middle and lower lobes of the right lung drained into the left auricle. While doing a closed intrapleural pneumonolysis on the left side a pulmonary vein from the upper lobe of the left lung was found draining into the left innominate vein. Since this lung was not removed and since it was viewed through a thoracoscope the interpretation may be erroneous.

When the various anomalies of the pulmonary veins are understood it is reasonable to expect that they will be recognized with greater frequency at the operating table. It is evident that these anomalies are of considerable surgical importance. This importance is mitigated by rarity and enhanced by common occurrence.

Pulmonary vein anomalies can be classified into two groups (1) an abnormal number of pulmonary veins emptying into the left atrium (2) abnormal drainage of the pulmonary veins (a) partial drainage into the right atrium or its tributaries (b) total drainage into the right atrium or its tributaries.

In performing a lobectomy by means of the individual ligation technique the presence of more than a single pulmonary vein must be demonstrated in order to avoid devitalizing the whole lung. When 3 veins are present on the right side the ligation of the vein draining the lobe is facilitated. The variable number of veins that may be found draining the lung is well recognized and described in the stand-

ard textbooks of anatomy (95). If the pulmonary veins were inspected inside the pericardium it seems reasonable to expect that a single pulmonary vein on either side would be of more common occurrence.

It has been recognized that the drainage of pulmonary blood into the major venous system or into the right atrium is a burden upon the heart. The thoracic surgeon endeavors to conserve healthy lung tissue when resection of the lung is necessary. It is important to recognize pulmonary venous anomalies when the thorax is open, since the removal of such a lobe of the lung would be beneficial to the patient by eliminating the burden placed upon the heart. Lobectomy of the lower lobe is more common than lobectomy of the upper lobe of the lung. If the pulmonary vein of an upper lobe drains into the major venous system and the normally draining lower lobe is removed it will increase the relative percentage of pulmonary blood drained into the major venous system. Accordingly it will increase the cardiac burden and should be removed. The most common anomalous pulmonary venous drainage is the drainage of the pulmonary vein from the upper lobe of the right lung into the superior vena cava.

For the thoracic surgeon it is frightening to contemplate the possibility of removing one lung only to find that the other lung drained its blood into the major venous system as in the patient described by Conant and Kurland. Fortunately the drainage of one lung into the major venous system is uncommon. Judged from case reports it occurs about as often as drainage of the total pulmonary blood into the right atrium or its tributaries. Actually, 31 such cases have been reported.

In the past a diagnosis of total drainage of pulmonary venous blood into the right atrium or its tributaries has not been made before death. In such patients death usually coincides with the closure of the foramen ovale. It is not unreasonable to believe that some day the condition will be diagnosed before death. If that were possible it would be interesting to speculate upon an operative attack. The interatrial septum might be removed or a major pulmonary vein could be anastomosed to the left atrium.

CONCLUSIONS

1 The anomalous drainage of pulmonary blood is being recognized with increasing frequency

2 When there is anomalous drainage of blood from the lung it drains into some structure arising from the primitive venous system.

3 An anomalous number of pulmonary veins draining into the left atrium is not uncommon and is recognized by the standard textbooks of anatomy

4 In the individual ligation technique for lobectomy of the lung it is important to demonstrate the presence of more than one pulmonary vein if devitalization of the whole lung is to be avoided.

5 If there is anomalous drainage of pulmonary blood into the major venous system the patient will be benefited by removal of the portion of lung thus drained

THE USE OF VASODILATION IN THE TREATMENT OF VENOUS THROMBOSIS

ALTON OCHSNER, M.D., F.A.C.S. New Orleans, Louisiana

THE rationale for vasodilatation obtained by sympathetic block in the treatment of venous thrombosis is that in true thrombophlebitis because of the irritative lesion within the vein impulses are set up and carried over the sympathetic nervous system to the arterioles and venules resulting in severe spasm. As we have emphasized previously (10-15) it is imperative to differentiate between two types of venous thrombosis one in which the thrombus is associated with and is dependent upon an inflammation of the vein wall i.e. thrombophlebitis and another in which the clot is a coagulation thrombus and occurs not as a result of an inflammatory process in the vein wall but because of two other factors a predisposing one consisting of increased coagulability of the blood caused by tissue damage and another, a precipitating one consisting of circulatory stasis which determines the site of the thrombus. These two types of venous thrombosis must be differentiated not only from an etiologic standpoint but also from the standpoint of their clinical manifestations their prognosis, and their treatment. Pathologically the clot in thrombophlebitis is a white or mixed thrombus. It is firmly attached to the vein wall and will not become detached. For this reason there is little or no danger of embolism except in the rare instance in which there is suppurative and in which because of liquefaction of the clot infected emboli can become detached. On the other hand in phlebothrombosis the clot is a red or coagulation thrombus. It is not firmly attached to the vein wall and can become detached easily. The patient with phlebothrombosis is a potential fatality and, although the symptoms

are minimal or lacking, there is great urgency for radical therapy. The symptomatology of the two conditions are entirely different. The patient with thrombophlebitis has definite symptoms which vary according to the location whether the deep or the superficial veins are involved. In femorotibial thrombophlebitis which is the most frequent type and which is a typical example of phlegmasia alba dolens the symptoms are maximal. There is pain and fever and the extremity is swollen white and cold. The significance of the paradox the whiteness and coldness of an extremity in an individual with pyrexia and whose surface temperature elsewhere is increased was not previously appreciated, but is now known to be due to concomitant spasm of the arterioles. These patients although having marked symptoms, do not succumb to the disease but unless adequate therapy is instituted early have persistent sequelae which last for years months or even for the duration of their lives. In the relatively rare case of superficial thrombophlebitis there is also pain and fever. In stead of the extremity being white and swollen as it is in the deep thrombophlebitis there is redness over the involved vein and there is minimal swelling. Superficial thrombophlebitis is usually seen in conjunction with varicose veins or is associated with peripheral arterial disease.

Whereas it is our belief that the treatment of phlebothrombosis consists of radical surgery i.e. ligation of the vein above the site of the thrombus or thrombectomy and ligation after removal of the thrombus, the treatment of thrombophlebitis should be conservative with the exception of the relatively rare case in which there is suppuration.

At the outset it should be emphasized that the treatment of venous thrombosis should consist principally of prophylaxis, and it is our belief that in most instances venous thrombosis can be prevented by the minimization of

Fig 1 Diagrammatic illustration showing the effect of experimentally produced thrombophlebitis on arteriolar pulsation. a, The normal findings in the veins, the arteries, and the arterial pulsations as determined plethysmographically. b, The decrease in the size of the arterioles following ligation of the common femoral vein. This results in decrease in the arteriolar pulsations. c, A marked decrease in the size of the arteriole and marked diminution in the arteriolar pulsation, following the production of chemical thrombophlebitis produced by injecting 40 per cent sodium salicylate into the isolated segment of vein. d, The return to normal of the lumen of the arteriole and the arteriolar pulsations following the blocking of the sympathetic impulses originating in the thrombophlebitic segment. This interruption is produced by anesthetization of the sympathetic ganglion.

trauma and infection and by the speeding of the circulation in the veins of the lower extremity venous thrombosis can be greatly minimized. Only after thrombosis has occurred is it necessary that active therapy be instituted. It is a rule on our service that in all patients past forty years of age who have any tissue injury operative accidental during delivery or as the result of destruction of tissue by neoplastic disease or infection the lower extremities are wrapped with compression bandages (Ace No. 8) from the toes to the groin in order to increase the rate of blood flow through the deep venous system. The patient is also made to contract the muscles of the calf and the thigh. Tight abdominal bandages are avoided and the return flow of blood through the venous system to the chest is favored by having the patient take deep breaths. Those positions such as the Fowler's position which favor circulatory retardation of the lower extremity are avoided.

Thrombophlebitis of the deep venous system, particularly the femoroflacc, is an interesting biologic phenomenon, because although the lesion is in the large deep veins, the symptoms are the result of arteriolar spasm. Where-

as previously it was thought that the pain was due to the inflammatory process in the veins, that the swelling was due to the plugging of the vein by the thrombus, and that the white discoloration was due to the lymphedema, we have been able to demonstrate experimentally and clinically that all of these manifestations are the result of vasospasm. Experimentally DeBakey, Burch, and I (3) showed that in an isolated thrombophlebitic segment of vein, impulses originate and are carried over the sympathetic nervous system producing spasm of the arterioles of the homolateral extremity (Fig 1). Subsequently we (16) showed in clinical cases of phlegmasia alba dolens that there is a very definite diminution in the arteriolar pulsation of the involved extremity which can be relieved by sympathetic block. (Fig 2). Concomitant with the relief of the vasospasm there are relief of pain, prompt subsidence of the fever and disappearance of the edema. That the edema is not secondary to the mechanical plugging of the vein by the thrombus is demonstrated by the fact that ligating a vein surgically will not produce a similar edema and that the edema in thrombophlebitis will subside quickly following the

chemical section of the sympathetics even though the thrombus still remains. The edema in thrombophlebitis and its persistence are undoubtedly due to the associated vasospasm of the homolateral arterioles, resulting in such a marked diminution in blood flow through the capillary bed that a relative anoxia of the capillary endothelium ensues. Because of this the permeability of the capillary endothelium is increased and there results an excessive exudation of fluid to the outside producing the edema. The edematous fluid has difficulty in getting back into the vascular system for two reasons, first, because the pump which is responsible for the movement of the lymph namely arteriolar pulsation is lost because of the arteriolar spasm and, second because spasm of the venules increases the pressure at the venule end of the capillary and inhibits absorption at this point. By overcoming the vasospasm by anesthetization of the sympathetic ganglia, the pain which is the result of ischemia is relieved and because of the prompt re-establishment of the normal circulation through the capillary bed the relative anoxia is overcome, the excessive exudation to the tissue spaces is prevented and by the re-establishment of the normal arteriolar pulsation the pump which is again brought into movement of lymph is again brought into action and the edema quickly diminishes. Prompt subsidence of fever following novocain anesthetization of the lumbar sympathetic ganglia in phlegmasia alba dolens is probably due to the more rapid resolution of the inflammatory process in the vein wall resulting from better vascularization.

Because of the demonstration of these vaso-spastic phenomena associated with thrombophlebitis and their relief by anesthetization of the regional sympathetic ganglia, the treatment of phlegmasia alba dolens by sympathetic block is rational. Also the fact that these patients who would otherwise be incapacitated for weeks or months with persistent post phlebitic edema, recurrent erysipeloid infections and recurrent ulcerations are well within a few days time is additional proof of the adequacy and efficacy of blocking of the sympathetic ganglia in the treatment of phlegmasia alba dolens.

Fig. 2. Diagrammatic illustration of the effect of thrombophlebitis on the arterial bed and on the arterial pulsations. As shown in a, impulses originating in the thrombophlebitic segment, which are carried over the sympathetic nervous system to the arterial bed, produce a marked decrease in the size of the lumen of the vessel and a diminution in pulsation. b, Following anesthetization of the sympathetic ganglia, there is an interruption of these vasoconstrictor impulses, resulting in a return of the arterial lumen to normal and a re-establishment of normal pulsation.

The technique of lumbar sympathetic block is extremely simple and has been described adequately in previous reports (13-15, 4, 16-18) (Fig. 3). Although, theoretically, the employment of a single needle is sufficient it is our belief that if one uses multiple needles the block is much more likely to be successful because at best the injection is done blindly. With multiple needles the chances of striking the level in which the sympathetic chain is located are greatly increased. Because the patient with phlegmasia alba dolens is usually quite ill we prefer performing the sympathetic block with the patient in the lateral decubitus position. Points two finger breadths lateral to the spinous processes of the first, second, third and fourth lumbar ganglia are chosen. A cutaneous wheal is made. A long fine special needle $5\frac{1}{2}$ inches in length, is used. It is important to use a long needle because otherwise the anesthetic solution may be deposited into psoas muscle. The needle is introduced perpendicular to the skin until the point hits the transverse process. The transverse process serves as a landmark, because, whereas there may be considerable difference in the thicknesses of the subcutaneous fat and the sacrospinalis muscle of a large, muscular,

unnecessary procedure when better results can be obtained more safely and more simply by sympathetic block with procaine.

CONCLUSIONS

1 Because the symptoms and signs in true uncomplicated deep vein thrombophlebitis (phlegmasia alba dolens) are due to spasm of the arterioles of the involved extremity vasodilatation produced by section with procaine of the regional sympathetic ganglia is rational

2 Although ligation of the involved vein is imperative in phlebothrombosis and in suppurative thrombophlebitis in order to prevent emboli gaining entrance to the systemic circulation sympathetic block is sufficient in suppurative thrombophlebitis

3 By the prompt induction of vasodilatation the symptoms and signs in phlegmasia alba dolens are quickly alleviated and the postphlebitic sequelae are eliminated.

4 The use of multiple needles in performing sympathetic block greatly enhances the efficacy of the injection

ANTICOAGULANTS IN VENOUS THROMBOSIS AND THE PREVENTION OF PULMONARY EMBOLISM

GORDON MURRAY M.D. F.R.C.S. (Can) F.R.C.S. (Eng) Toronto, Canada

THE object of this paper is to discuss the effect of anticoagulants in the treatment of venous thrombosis, its prevention and the prevention and treatment of pulmonary embolism.

To approach this problem it seemed logical to consider the subject under the following headings:

1 Whether or not venous thrombosis is in factive in origin. It is my impression as stated in a previous paper (7) that in only 0.5 per cent of the cases of venous thrombosis was infection a factor in production of the thrombus and even in these cases it is possible that the infection was a secondary invasion of a thrombus or clot which had formed from other sources. This evidence is based on the fact that in 28 cases of venous thrombosis which were operated upon, cultures taken from the surrounding tissue from the wall of the vessel and from its lumen, showed no growth of organisms on ordinary cultures, aerobic cultures or on special media. The fact also that in the majority of cases if the extension of thrombosis can be prevented they clear up rapidly without further evidence of infection or suppuration leads further support to this view.

2 The beginning and extension of the thrombus. On clinical evidence, which was supported also by experimental evidence, I think it can be safely assumed that whatever may be the factors precipitating the thrombosis the lesion begins in a localized area and extends from such area as a propagating thrombus. This is well demonstrated in the cases in which the clinical signs and symptoms would indicate that the calf muscles may be the site of origin. From that point the progression of thrombosis with clinical symptoms

and signs extends through the adductor region to involve the femoral and presently the iliac vessels. In many cases at a later period the opposite leg is involved in what would appear to be a retrograde fashion. Also in the post mortem study of the vascular tree of the lungs in patients dying of pulmonary embolism, the primary embolus has been well demonstrated and on top of that has been built up a thrombus which is of more recent duration which extends more widely through the vascular tree until ultimately a fatal effect is produced—a fact which has been well demonstrated by Professor Boyd.

3 Ligation of vessels an exciting cause. There is evidence to suggest both clinically and experimentally that ligation of vessels, especially veins, may be the exciting cause for thrombosis, from which extension can occur. This is well known in operations involving dissection and removal of organs in the pelvic region where thrombosis with pulmonary embolism as a complication, is a fairly common occurrence. It has been demonstrated experimentally that if any major or minor vessel is divided tied sewn or allowed to become occluded by natural clotting and thrombosis that there is a process of thrombosis set up which extends proximally through that vessel for varying distances. In a vessel very carefully dealt with these thrombi may be only small fragments occurring in clinks in the vessel where it is gathered into a cone by ligation or where there are small irregularities from suture of the end of the vessel. However once this process is set in action it is purely a matter of accident just how far it will extend, if the other conditions favoring thrombosis are present. It is suggested, therefore, that any form of surgery on the vascular tree, especially on the venous side, is not without some hazard as regards the initiation of this process of thrombosis with the unpredictable accident of pulmonary embolism as a complication.

From the Department of Surgery, Toronto General Hospital.
Presented at the Symposium on Venous Thrombosis and Prevention of Pulmonary Embolism before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

It would seem obvious therefore, if thrombosis and clotting can be prevented or is not initiated that pulmonary embolism cannot occur leaving out for the moment, of course fat embolism. Much has been done in the way of clinical care of patients in an attempt to prevent early thrombosis in the vascular tree and from statistics in our own hospital the incidence of thrombosis and pulmonary embolism has been considerably reduced by care of the patient on the operating table and the avoidance of many of the conditions which are conducive to thrombosis. It may be stated emphatically that with the ultimate in view if by any means including giving anticoagulants, thrombosis in the venous tree could be prevented then the solution of pulmonary embolism and the late effects of thrombosis in vessels would be eliminated. It is obvious, of course that there are difficulties and objections to giving anticoagulants with this objective. For example there are groups of patients in whom the administration of an anticoagulant must be undertaken with great caution. In the postoperative group there may be the danger of initiating hemorrhage into the wound or in the operative field. However if the surgeon has in mind that an anticoagulant may be used, if the larger or medium sized vessels are adequately dealt with by ligatures, the danger of this is exceedingly small and this danger can be reduced to an absolute minimum by the careful administration of the anticoagulant and its proper control so that the clotting times and prothrombin times are kept within normal and reasonable limits as advocated in the early studies on these subjects. As well there is the added work and difficulty required in such treatment. However with the proper control and a fine understanding of the objective and the principles, these difficulties are not insuperable and in my experience they justify the end results.

I quite agree, for example in varicose veins with localized thrombosis in a varix, that ligation with continued activity of the patient offers simple and adequate relief of symptoms and almost certainly eliminates or prevents complications such as pulmonary embolism or extension to the main vascular tree. On the other hand with widespread thrombosis

through an uncertain area, it is more difficult to know just where ligation would be effective in loculating the area of thrombosis, to prevent further embolism. In my experience the question regarding the terminology of phlebotrombosis versus thrombophlebitis rests on the knowledge of the pathology of the course of events in thrombosis in the venous tree. As every operator has demonstrated, there may be thrombosis of vessels far in advance of the area suggested by clinical symptoms or physical findings of edema, tenderness, etc. As was explained in an earlier paper I believe these effects are as stated by Dr Homans many years ago the result of the inflammatory reaction to a thrombus which has formed some hours or days previously. These inflammatory changes provide the patient with the cause of his symptoms, and the surgeon, with the findings of thrombosis. It is obvious, therefore, that the extent of the thrombus in the vascular tree is exceedingly difficult to delineate by physical examination. Also phlebography has given only partial satisfaction in delineating the uppermost extension of such a thrombus. As the surgeon has the objective in tying vessels, of loculating the process below his figure difficulties immediately arise. It is just here that anticoagulants enter into their best atmosphere. The effect throughout the vascular tree is universal and thrombosis, no matter where it is or where its extensions may proceed comes under the influence of anticoagulants. This is just as true in the question of further extension of thrombosis when embolism has occurred in the pulmonary artery as well as in the distal tree. It also has the advantages of having its effect in preventing intracardiac thrombosis (5). Especially is it true in the prevention of thrombosis in surgery either on the arteries (6) or on the veins themselves. I have found it of very great value in doing anastomoses as first done by Blalock, and have used it in 15 cases of the Tetralogy of Fallot. In none of these patients has there been thrombosis at the site of anastomosis as far as one can determine clinically and in none has there been cerebral thrombosis or other cerebral accidents neither has there been any evidence of pulmonary or peripheral embolism.

My evidence as regards the effect of anti-coagulants on venous thrombosis and pulmonary embolism, is based on

1 Four hundred postoperative cases in which patients were treated with an anticoagulant with the objective of cutting down the incidence of thrombosis and consequently of pulmonary embolism. In this group no patient developed peripheral thrombosis and there were no cases of pulmonary embolism. Our experiment obviously includes too few cases to be of much significance except that the treatment was carried out in groups of cases in which from our hospital statistics, thrombosis and pulmonary embolism reached the highest figures recorded.

2 Three hundred and seventy-one cases of venous thrombosis in which treatment by anticoagulants was carried out with the objective of (a) preventing pulmonary embolism and (b) as treatment for the progressive thrombosis in the venous tree with a hope of relieving symptoms and of diminishing the ill effects so obvious and evident following venous thrombosis, such as persistent edema, varicose veins, ulceration, etc. All these patients had typical symptoms and signs of venous thrombosis before treatment was started.

The results of treatment were satisfactory in that none of the patients had pulmonary embolism. Moreover the late effects of the thrombosis were less severe than in a control group. There was less persisting edema, fewer ulcers in a 9 year period and fewer varicose veins during this time.

3 One hundred and forty nine cases of pulmonary embolism treated by anticoagulants. The cases were not selected and were obviously those which had survived the first embolism. In many of these the patients were in extremis at the time of beginning of treatment. Fifty two of these presented a state with which you are all familiar, the patient in alarming shock with no palpable pulse at the wrist, bordering on unconsciousness and with all the serious and dreadful effects of massive pulmonary embolism. From an analysis of histories of the hospital together with the postmortem findings, it has been demonstrated as shown on a previous paper that about 1 in 5 of all cases surviving the first pulmonary embolism is apt

to succumb to future embolisms or from the effect of propagating thrombosis increasing the effect of the original or subsequent emboli.

This group of patients with pulmonary embolisms here reported are those over whom I had control during treatment. In these I had information that the treatment was adequate that the necessary effect on the clotting time or on the prothrombin time was obtained. I saw a fairly large number of similar cases in consultation with other doctors who undertook the treatment of the patients and for that reason these are not included in this report. I have learned subsequently of 3 deaths in this group treated by other doctors. In those in whom I had control of the treatment and knew that the adequate effects on the clotting and prothrombin times had been obtained there were no deaths from embolism in 149 cases. Four of these following the beginning of treatment, had further embolisms which were obviously small in nature because they produced only slight effects on the patient.

It is very impressive to see the effect on a patient with massive pulmonary embolism or with extensive thrombophlebitis or both the improvement that takes place in a matter of very few hours is striking once the effect on clotting time has been obtained. The pulmonary distress with dyspnea, pain etc. together with the embarrassment of heart action are diminished progressively in relatively short time so that within a few hours there is a measurable change and within 24 to 36 hours the alarming symptoms have largely disappeared. It may take several more days before there is complete relief of all symptoms.

During the course of such treatment, it has frequently been observed that there was no obvious swelling or edema of extremities at the time of the massive embolism. However, during the course of treatment one leg has enlarged and showed "quite marked edema on some occasions at the same time, or within a few days the other leg has gone through similar changes. It is my impression from a study of the pathology that this is no indication of ineffectiveness of the treatment by anticoagulants. I believe that at the time of the embolism there obviously was a massive thrombus at some site in the venous tree

which was so insecurely attached that it broke off and floated as an embolus. However at this stage the inflammatory reaction in the wall of the vein and surrounding tissue had not reached the point where it had produced clinical symptoms. Even under the treatment by the anticoagulant, which can only prevent the further extension of thrombosis, the remaining thrombi have excited the inflammatory reaction which has gone through the changes necessary to healing of the lesion.

To accomplish this effect, in the presence of thrombosis or embolism, it is absolutely essential that the original principles of application of anticoagulants be followed. First, if heparin is administered it must be carried to the point where the clotting time in the patient is kept at or about 15 minutes. It is of no use whatever to give heparin blindly and not know that the effect is being obtained. Because the effect of heparin is so evanescent and because the dose is variable for the individual, the only safe way to be sure of this effect is to do clotting times at short intervals. The next principle is to give the anticoagulant until the healing process in the area of existing thrombosis has reached the stage where no further thrombosis will take place. From our experience in the average patient who is able to get out of bed the patient is kept at rest for 3 or 4 days under the treatment. Following this exercise is encouraged and within 6 or 7 days of the beginning of treatment the patient is urged to be out of bed and exercising actively. When the patient can go through this with some energy probably on the seventh, eighth, or ninth day the heparin treatment is discontinued. If however the patient has some lesion or operation which necessitates staying in bed then the treatment is continued for longer periods up to 3 and occasionally 4 weeks, in such cases as spinal fusion where the patient has not been allowed to be out of bed. It was demonstrated experimentally that a thrombus placed in a vessel is endothelialized well within this period of time and probably that is the best protection against further extension provided the remaining physiology of the patient has reached normal.

Dicoumarol has many advantages over heparin in the way of expense and the ease of

administration. However in my experience it is not quite as effective as is heparin, in preventing extension of thrombosis. It can be used however as an important adjunct. When the patient has begun treatment with heparin for 2 or 3 days, the dicoumarol can be added as a supplement and the patient encouraged to be ambulatory under this treatment with greater ease.

I have not used any of the thrombolytic substances in an attempt to dissolve clots. A few patients were treated with sodium tetrathionate, but not enough to determine its value. In those treated the effect seemed to be excellent.

Dr. Allen at the Mayo clinic has reported (1) a large group in which anticoagulants were administered with excellent effects. Also the group in Scandinavia namely Zilliacus, Hedenfus, Jorpes have reported large groups treated with anticoagulants with satisfaction.

One advantage of using anticoagulants also is that in a patient who is on the verge of collapse the treatment involves very little disturbance and in my experience the effect has been dramatic. This may have advantages over operative procedures where either injection or operation involves the undertaking of more active and energetic measures for which a patient may be in very poor condition.

CONCLUSIONS

1. Intravascular thrombosis and clotting can be prevented by anticoagulants, heparin, and dicoumarol.

2. If thrombosis and clotting have occurred, anticoagulants in appropriate doses will prevent further extension of the process.

3. If a patient is adequately treated with anticoagulants following pulmonary embolism, the chances of survival are excellent.

CARCINOMA OF THE COLON

A Statistical Analysis

WILLIAM J VYNALEK, M.D. F.A.C.S. Berwyn Illinois, LESLIE L. SAYLOR M.D. Topeka Kansas, and ROBERT SCHREK M.D., Hines, Illinois

THIS paper represents a study of all the patients with carcinoma of the colon not including the rectum and sigmoid admitted to the Veterans Administration Hospital, Hines Illinois from 1931 to 1945 inclusive. A similar review is being made by other workers at this Hospital on carcinoma of the rectum and sigmoid. During this 15 year period this institution has been the tumor center for all Veterans hospitals of the Midwest and a large volume of material and records is available for study and analysis.

The purpose of this paper is to add to the growing number of cases being reported so that totals of statistical significance may be amassed to analyze the material and to attempt to draw pertinent conclusions. Each record of admission was studied with reference to age, duration of symptoms common complaints, important physical and laboratory findings, surgery operative and numbers and length of survivals. It is a difficult task to take a maze of data and present conclusions in a simple readable form. Follow up records are practically one hundred per cent complete because of government pension regulations and the persistent efforts of a specially created tumor registry section.

There were 131 279 admissions of all types during this 15 year period and 16 097 (primary admissions) of these were patients with carcinoma. In 1330 of these admissions, the primary lesions were in the large bowel colon, and rectum included. In Figure 1 are shown

Published with permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

Presented in the forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20 1946.

the sites of predilection. Many writers have repeatedly stressed that two-thirds of all carcinomas of the large bowel involve the rectum and rectosigmoid and can be felt by the finger of the careful examiner. These and certain others in the lower sigmoid likely to be missed by barium enema can be seen through the proctosigmoidoscope and specimens obtained for biopsy study. Points of flexure and the cecum have a moderately high incidence considering their short span. They presumably receive the maximum mechanical and chemical trauma which might play a rôle in carcinoma of the colon.

The close similarity in the frequency of the sites of involvement in our patients with those reported by others is shown in Table I and is of biological significance.

This study concerns itself primarily with the 486 patients who had involvement above the rectosigmoid. The histories were divided into two groups before and after January 1 1941. This division is convenient because it gives data as to 5 year cures and because of the adoption of improved methods in anesthesia and in preoperative and postoperative care in the latter period. These included better colon decompression, the various sulfa drugs later penicillin, and liberal use of blood transfusions and continuous gastric suction. Their salubrious effect on surgical mortality and morbidity seems clinically and statistically to have ushered in a new era in colon surgery.

In Figure 2 are given percentages of resectability for the entire period. In the term resectable are included only those cases in which a cure can reasonably be anticipated following removal of all gross carcinomatous tissue. It includes those in which adjacent resectable organs and lymph glands are involved. A non resectable lesion implies distant metastatic spread to liver lung bone brain or non removable lymph glands. In the nonresectable

which was so insecurely attached that it broke off and floated as an embolus. However at this stage the inflammatory reaction in the wall of the vein and surrounding tissue had not reached the point where it had produced clinical symptoms. Even under the treatment by the anticoagulant which can only prevent the further extension of thrombosis, the remaining thrombi have excited the inflammatory reaction which has gone through the changes necessary to healing of the lesion.

To accomplish this effect, in the presence of thrombosis or embolism it is absolutely essential that the original principles of application of anticoagulants be followed. First, if heparin is administered it must be carried to the point where the clotting time in the patient is kept at or about 15 minutes. It is of no use whatever to give heparin blindly and not know that the effect is being obtained. Because the effect of heparin is so evanescent and because the dose is variable for the individual the only safe way to be sure of this effect is to do clotting times at short intervals. The next principle is to give the anticoagulant until the healing process in the area of existing thrombosis has reached the stage where no further thrombosis will take place. From our experience, in the average patient who is able to get out of bed the patient is kept at rest for 3 or 4 days under the treatment. Following this, exercise is encouraged and within 6 or 7 days of the beginning of treatment, the patient is urged to be out of bed and exercising actively. When the patient can go through this with some energy probably on the seventh eighth or ninth day the heparin treatment is discontinued. If however the patient has some lesion or operation which necessitates staying in bed then the treatment is continued for longer periods up to 3 and occasionally 4 weeks, in such cases as spinal fusion where the patient has not been allowed to be out of bed. It was demonstrated experimentally that a thrombus placed in a vessel is endothelialized well within this period of time and probably that is the best protection against further extension provided the remaining physiology of the patient has reached normal.

Dicoumarol has many advantages over heparin in the way of expense and the ease of

administration. However in my experience it is not quite as effective as is heparin, in preventing extension of thrombosis. It can be used however as an important adjunct. When the patient has begun treatment with heparin for 2 or 3 days, the dicoumarol can be added as a supplement and the patient encouraged to be ambulatory under this treatment with greater ease.

I have not used any of the thrombolytic substances in an attempt to dissolve clots. A few patients were treated with sodium tetrathionate but not enough to determine its value. In those treated the effect seemed to be excellent.

Dr. Allen at the Mayo clinic has reported (1) a large group in which anticoagulants were administered with excellent effects. Also the group in Scandinavia namely Zilliacus, Hedenius, Jorpes have reported large groups treated with anticoagulants with satisfaction.

One advantage of using anticoagulants also is that in a patient who is on the verge of collapse the treatment involves very little disturbance and in my experience the effect has been dramatic. This may have advantages over operative procedures where either injection or operation involves the undertaking of more active and energetic measures for which a patient may be in very poor condition.

CONCLUSIONS

1 Intravascular thrombosis and clotting can be prevented by anticoagulants, heparin, and dicoumarol.

2 If thrombosis and clotting have occurred, anticoagulants in appropriate doses will prevent further extension of the process.

3 If a patient is adequately treated with anticoagulants following pulmonary embolism, the chances of survival are excellent.

CARCINOMA OF THE COLON

A Statistical Analysis

WILLIAM J. VYNALEK, M.D. F.A.C.S. Berwyn Illinois
Kansas, and ROBERT SCHREK, M.D. Hines, Illinois
LESLIE L. SAYLOR M.D. Topeka,

THIS paper represents a study of all the patients with carcinoma of the colon, not including the rectum and rectosigmoid, admitted to the Veterans Administration Hospital Hines Illinois from 1931 to 1945 inclusive. A similar review is being made by other workers at this Hospital on carcinoma of the rectum and rectosigmoid. During this 15 year period this institution has been the tumor center for all Veterans hospitals of the Midwest, and a large volume of material and records is available for study and analysis.

The purpose of this paper is to add to the growing number of cases being reported so that totals of statistical significance may be amassed to analyze the material and to attempt to draw pertinent conclusions. Each record of admission was studied with reference to age duration of symptoms, common complaints important physical and laboratory findings surgery operative mortality effects of irradiation pathology and numbers and length of survivals. It is a difficult task to take a maze of data and present conclusions in a simple readable form. Follow up records are practically one hundred per cent complete because of government pension regulations and the persistent efforts of a specially created tumor registry section.

There were 131 279 admissions of all types during this 15 year period and 16 097 (primary admissions) of these were patients with carcinoma. In 1330 of these admissions the primary lesions were in the large bowel colon and rectum included. In Figure 1 are shown

Published with permission of the Chief Medical Director Department of Medicine and Surgery Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

the sites of predilection. Many writers have repeatedly stressed that two-thirds of all carcinomas of the large bowel involve the rectum and rectosigmoid and can be felt by the finger of the careful examiner. These and certain others in the lower sigmoid likely to be missed by barium enema can be seen through the proctosigmoidoscope, and specimens obtained for biopsy study. Points of flexure and the cecum have a moderately high incidence considering their short span. They presumably receive the maximum mechanical and chemical trauma which might play a rôle in carcinoma of the colon.

The close similarity in the frequency of the sites of involvement in our patients with those reported by others is shown in Table I and is of histological significance.

This study concerns itself primarily with the 486 patients who had involvement above the rectosigmoid. The histories were divided into two groups, before and after January 1 1941. This division is convenient because it gives data as to 5 year cures and because of the adoption of improved methods in anesthesia and in preoperative and postoperative care in the latter period. These included better colon decompression the various sulfa drugs later penicillin and liberal use of blood transfusions and continuous gastric suction. Their salutary effect on surgical mortality and morbidity seems clinically and statistically to have ushered in a new era in colon surgery.

In Figure 2 are given percentages of resectability for the entire period. In the term resectable are included only those cases in which a cure can reasonably be anticipated following removal of all gross carcinomatous tissue. It includes those in which adjacent resectable organs and lymph glands are involved. A non resectable lesion implies distant metastatic spread to liver lung bone, brain or non removable lymph glands. In the nonresectable

Fig. 5. Number of one and multistaged resections of carcinoma of colon and operative mortality

Resections in all segments of the colon reflects this statistically significant lowering of the operating mortality but the right half of the colon is especially favored. Pack and Livingston state that an operative mortality of 10 to 15 per cent can be expected if there is no selection of cases. However with some clinics reporting a surgical mortality of less than 4 per cent, there is ample room for improvement in our results.

Figure 4 shows the operative mortality by years. The change began gradually during 1940 and is striking thereafter. It cannot be attributed to improvement of surgical technique.

In Figure 5 it is noted that resections were done in one stage in only 25 per cent of the 1931-1940 cases, but in 51.6 per cent in the 1941-1945 group. Although the mortality in single and multiple stage procedures in the 1941-1945 group is about the same the increased number of one stage procedures possible is of great significance since it reduced the period of hospitalization from 2 months or more to 3 weeks or less, and it added to the comfort of the patient. With the present day shortage of hospital beds, the successful shift to one stage procedures is of tremendous value and is in line with the general trend throughout the nation. The good reason for the early tendency toward multiple stage procedures in the 1931-1940 period is indicated by the mortality rate of 56.2 per cent for the

one stage, contrasted with 29.1 per cent for the other.

In Figure 6 the survivals of 5 to 15 years following resections in the 1931-1940 group are shown. Of the 281 colon cases admitted in this first period, omitting those resected or explored elsewhere and sent here for routine x ray therapy or terminal care 193 candidates were left for possible resection. In 64 resection was accomplished and 21 or 32.8 per cent of the resectables are alive today. Of the resectables who survived the operation in that first period when the mortality rate was so high, 51.2 per cent are alive over 5 years. With the lowered mortality rate of the second period, it is to be expected that approximately 50 per cent of the resectables can be offered a 5 year cure and this is the approximate figure of the most successful tumor clinics. Post operative prognosis is best in right side lesions.

In 41 cases resection was done elsewhere in the 1931-40 group and the patients were sent to Hines for routine x ray therapy or terminal care. Of these 13 or 32 per cent, were alive 5 to 15 years later. Improvement in the surgical mortality rate is gradually reaching a point where for further progress the only means of obtaining more cures is to make earlier diagnoses to increase the percentage of resectables. Herein lies considerable room for improvement.

Figure 7 presents a comparison of the survival of patients following curative resection

ANALEK ET AL. CARCINOMA OF COLON

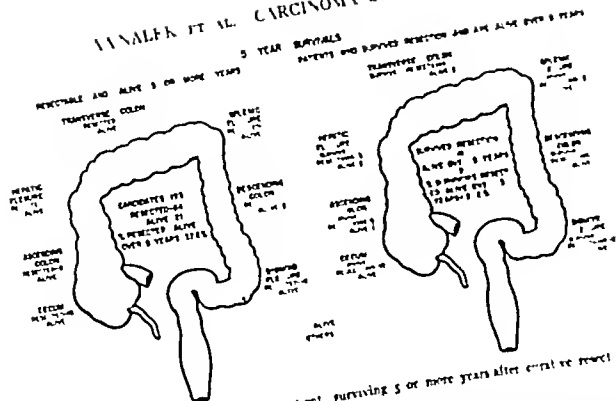

Fig. 6. Number and percentage of patient surviving 5 or more years after curative resection of the colon, 1931-1949

for carcinoma of the colon in 1931 to 1940 and in 1941 to 1945. The method of construction of the graph is shown in Table II.

During 1931 to 1940 there were 64 patients with resections. Of these 64 per cent survived 1 month after the operation, 44 per cent 3 years and 30 per cent 5 years. To compare the survival of the patients operated on during 1941 to 1945 it is necessary to analyze the data by years as shown in the table. In 1941 10 patients were resected. Of these men 9 survived 1 month and 7 men survived 3 years. As the cases were analyzed early in 1946 the 1941 patients were followed only 4 years. The 1942 cases 3 years, and for the 1945 patients only the 1 month follow up can be used. The results obtained on the 1941 to 1945 patients can be totaled as shown in the table and the percentage of survivors calculated for the entire 1941-1945 group. By this method it is possible to obtain survival curves for the patients that have been operated on within the last five years.

It is seen from Figure 7 and Table II that there has been considerable improvement in the survival of patients after operation. A large part if not all of this improvement is evidently due to the fact that a greater percentage of patients died postoperatively in

1931 to 1940 than in later years. To determine whether the improvement in survival is due exclusively to the decrease in postoperative deaths it was necessary to construct Figure 8 which shows the follow up of patients who survived 1 month or more after resection. Even after the postoperative deaths are excluded there is still a higher percentage of survival in the patients operated on in 1941 to 1945. This suggests that surgeons in recent years were capable of removing completely the

tumor in a higher percentage of cases than formerly

SYMPTOMS

These patients were all veterans the majority from World War I. They were all males, the youngest was 21 the oldest 77 and in most cases the carcinomas occurred between the ages of 45 and 50 years. Symptoms were present from sudden onset to several years before a diagnosis was made. An average of 6 months passed between the onset of symptoms and hospitalization. In those found resectable the average duration was 6.3 months, in the nonresectable group 9.7 months. Lahey states that at that clinic the interval for all cases has been 9 months with no appreciable improvement in recent years.

There are no pathognomonic symptoms of cancer of the large bowel but sufficient warning is given to justify study which will usually lead to an accurate diagnosis. Unfortunately many patients still undergo trial medical treatment, hemorrhoidectomies, or appendectomies before diagnostic studies are instituted. The most common and suspicious complaints are enumerated as follows (Fig 9)

1. *Abdominal distress* frequently marked in the region involved, though often enough to cause confusion, obstruction of the left colon may cause most distress in the dilated right bowel. The character of the distress varies and seems to be directly related to the degree of obstruction. It may be dull, but as the lesion tends to be located more toward the left with its semisolid stool and a tendency toward the formation of annular constricting lesions, obstructive pain occurs with colic, nausea, and vomiting. Discomfort is usually aggravated by eating and relieved by bowel movements especially if the stools are kept liquefied by cathartics. In 7 per cent of left colon lesions an acute obstruction ushered in the first sign of trouble. Fourteen per cent of splenic flexure lesions began in this manner. Gordon Heyd states that 5 per cent of sigmoid tumors begin with acute obstruction. Carcinoma of the cecum is frequently diagnosed clinically as an appendicitis, and appendectomies had been performed on 19 of the cecal cases just before admission to this hospital. Usually the surgeon recognized that there was cecal pathology present at operation.

VYNÁLEK ET AL. CARCINOMA OF COLON

SYMPTOMS

LEFT HALF COLON
OBSTRUCTIVE SYMPTOMS
CHANGE IN BOWEL HABITS
BLOOD IN STOOLS

FINDINGS

Fig 9. Symptoms and signs in patients with carcinoma of the colon.

2 *Change in bowel habits* is an important and frequent symptom elicited only by a carefully taken history. Constipation is common regardless of the location of the lesion but more pronounced and annoying in left half colon pathology. It frequently alternates with diarrhea, often because the patient does himself with cathartics at regular intervals. However, diarrhea instead of constipation may be the patient's complaint.

3 *Mass in the abdomen* was mentioned by the patient himself in 25 per cent of the cases with involvement of the cecum or ascending colon, 6 per cent of the sigmoid group and rarely by others. Gordon Heyd states that 10 per cent of the people with carcinoma of the cecum discover a lump in the right side before consulting a physician.

4 *Weight loss*, contrary to the usual belief is often an early sign and is present in practically all. It may occur rapidly but ordinarily appears slowly. From 16 to 75 pounds loss of weight was common but in some patients with a violent obstructive onset there had been no previous loss.

5 *Blood in the stools* is mentioned in the histories of 33 per cent of patients with lesions in the left half of the bowel with their tendency toward the appearance of conspicuous red

blood but only 8 per cent of those with right colon involvement mentioned melena. Unfortunately the record often fails to note any questioning on this important point.

6 *Other complaints*. Anemia, of an intense degree is always stressed in the literature in connection with cancer of the cecum. It is spectacular and impressive when it occurs but was uncommon in this series. The red count was usually normal even in the cecal cases until late in the disease when curative surgery was impossible. Only 13 of the 102 cecal cases had a red blood count below 3,000,000. In only 2 patients anemia and weakness were the main complaints. Of the 53 ascending colon lesions, 6 had a red blood count below 3,000,000.

Indigestion, weakness, nausea, vomiting, anorexia and fever were frequently mentioned.

FINDINGS

1 *A palpable mass* was noted at the initial examination by the Veterans Hospital physician in 81 of the 102 cecal cases, 14 of the 53 ascending colons, 20 of the 27 hepatic flexure colons, 26 of the 55 transverse colons, 11 of the 27 splenic flexures, 22 of the 49 descending colons, 87 of the 173 sigmoids, averaging 69 per cent.

This is a rather high figure compared to that of others who mention 10 per cent to 33½ per cent as having palpable masses on the right, seldom on the left, and again indicates that many of our patients arrive late. However the palpation of a tumor does not necessarily indicate a hopeless process.

2 *Tenderness* of varying degree is frequently present at the site of involvement.

3 *Occult blood* in the stool was surprisingly seldom searched for but usually positive if the tests were ordered.

4 *Barium enema x ray studies* practically always revealed a suspicion-arousing defect which was usually properly interpreted. The segment where pathology was most often overlooked was the sigmoid in which x ray studies missed the lesion in 9 per cent of these cases.

5 *Proctoscopy* following digital rectal examination is without a peer in lesions up to 23 centimeters from the anus.

PATHOLOGY

Pathology was proved by microscopic studies in 68 per cent of the series. Autopsies were secured in 145 (37%) of the 390 known dead.

Adenocarcinoma or a colloid modification was the usual finding occasionally an undifferentiated carcinoma. In lesions thought by the operator to be nonresectable a large firm mesenteric gland was frequently taken for biopsy and the pathologist's report was usually negative for carcinoma. This implies that neither surgeon nor pathologist is able to diagnose cancer of the lymph nodes grossly or to differentiate from inflammation. A frozen section at operation might prevent classifying a condition as inoperable.

Operative deaths were usually due to peritonitis, embolism, pneumonia, shock and myocardial damage. One cecal case succumbed to gangrene of the terminal small bowel after resection due to thrombosis of the ileocolic artery.

Multiple polyposis was noted by the pathologist, surgeon, proctologist or roentgenologist in 11 (2%) of the 486 patients of this study. The primary carcinoma in these cases was located as follows: cecum, 2; transverse colon, 3; splenic flexure, 1 (this patient also

had a concomitant cancer of the hepatic flexure); descending colon, 4; and sigmoid, 1.

In 3 instances in this entire series multiple cancers of the large bowel were found. Perforations into small bowel and stomach were noted in a few instances. Bladder attachment, but not perforation, was occasionally mentioned. Hydronephrosis secondary to crinomatous obstruction of the ureter seldom occurred. Abscesses often complicated the picture, and required preliminary drainage.

IRRADIATION

Irradiation was used frequently as a palliative measure in the earlier years with no outstanding improvements. Doses of a total of 100 to 6000 roentgens are reported, but deep therapy is no longer considered of much value for lesions above the rectosigmoid. It was felt that x ray therapy following drainage of abscesses definitely shortened the period of waiting preparatory to radical surgery.

AVERAGE SPAN OF LIFE

In the inoperable cases death occurred 11 months after onset of symptoms, a speed which suggests a vicious process. In those having a simple exploration death occurred 6 months after operation and 16 months after onset of symptoms. Those who underwent palliative resections lived 17 months after operation. As had been shown previously the majority who died after attempted curative resections did so in the first and second years but some died of recurrence as late as 6 years following operation.

SUMMARY

A survey has been made of the 486 cases of carcinoma of the colon seen at Hines Veterans Hospital, Hines, Illinois, during the past 15 years. The sites of predilection are almost identical with large groups reported elsewhere. The resectability rate of 35.6 per cent is low. The drop in the mortality rate following surgery from 35.9 to 9.7 per cent in recent years is encouraging. The 5 year survival rate approaches the 50 per cent figure of the larger clinics. More one stage procedures are being done in recent years. A review of pertinent data is given.

ANTICOAGULANT THERAPY IN THROMBOSIS

J ERIK JORPES, M.D Stockholm Sweden

THE specific treatment of thrombosis seems to demand the use of anticoagulants. Thrombosis arises through intravascular clotting of the blood a pulmonary embolism is simply a fibrin clot detached from the walls of a peripheral vessel. In the past considerable attention has been paid by such men as Morawitz, Howell and others to the possibility of using anticoagulants to prevent thrombosis. Although heparin the natural anticoagulant of the body itself was discovered in 1916 by MacLean working with Howell, very little benefit came of it during the next 20 years. As early as 1933 Charles and Scott of Toronto elaborated a method for large scale extraction of heparin from liver and lungs and the chemical nature of the drug was elucidated 2 years later (Jorpes). Thanks to these efforts heparin has been made available. Crafoord of Sweden and Murray of Toronto were the two surgeons first to use heparin clinically.

PROPHYLACTIC USE OF HEPARIN

During the years 1935 to 1940 it was clearly demonstrated that postoperative thrombosis and pulmonary embolism could be prevented if heparin were administered in adequate doses over an adequate length of time. In Sweden Crafoord Wetterdal and Leissner heparinized about 800 patients postoperative-

ly and in Canada Murray reported the results in treating 400 patients in the same way. Although a high incidence of thrombosis was expected 2 or even 4 per cent, practically no complications occurred. Two hundred fifty milligrams of heparin a day was found to be an adequate dosage. In the Swedish series heparin was given to 657 patients, the treatment being started on the second or third day after operation or childbirth.

Similar successful results have been reported from the use of dicoumarol. Barker and his co-workers at the Mayo Clinic administered dicoumarol postoperatively to 1,000 patients and in Sweden Bruzelius treated 1,600 patients in the same way. In each series there was a marked decrease in the number of thrombotic complications.

Because of the expense involved and the risk of hemorrhage there will however, be no question about giving heparin or dicoumarol to every patient after operations or childbirth. Prophylactic treatment with anticoagulants must be restricted to cases in which the risk of a thrombosis occurring is considerable e.g. after parturition in a patient who has had thrombosis during pregnancy or after operations on patients who have suffered from earlier repeated thromboembolic attacks after operation, childbirth, or miscarriage. In such instances heparin has frequently been used in Swedish hospitals, starting with 50+50+50+100 milligrams of heparin a day at 8, 12, 16 and 20 hours from the second or third day onward for 5 to 8 days, until the patient is able to get up and can move about freely.

Presented at the symposium on Venous Thrombosis and Prevention of Pulmonary Embolism before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

only were quite without discomfort. The 13 remaining had symptoms in the leg. All suffered from swelling of the lower part of the leg in most instances moderate to severe. Five had in addition swelling of the thigh. 3 had severe pain and a feeling of heaviness in the leg.

At Bauer's clinic, where all cases except those with thrombosis diagnosed before their arrival at the hospital received early heparin treatment, the process did not progress beyond the calf in 80 per cent of the cases and it stayed in the calf in all cases where heparin was given before a phlegmasia had developed. From Zilliacus's data on conservatively treated cases, it appeared that thrombosis spread to the thigh in 80 per cent of the cases. In his series of cases treated with anticoagulants—the cases presumably were not treated in the most efficient manner as far as early diagnosis and therapy were concerned—the process spread to the thigh in spite of the specific therapy in 55 per cent of the cases.

It was noted by Zilliacus that when the thrombosis had extended to the thigh there was little difference between the conservatively treated cases and those treated with heparin. Swelling of the calf with discoloration induration with large varicose veins were present in most of the cases of both groups. Ulcus cruris occurred in 11 of 154 cases treated with heparin and submitted to follow-up examination. The result in this group was the same as that among the conservatively treated cases. An important difference, however, as compared with the conservatively treated cases,

was that bilateral symptoms occurred only in 3 cases instead of in 33 per cent as found among the conservatively treated cases.

The sequelae in the patients with thrombosis of the calf who were treated with heparin were generally mild. Of 130 such cases 66 were completely free from symptoms, while the remaining patients showed only swelling of the calf after exertion. Only 1 patient in this group suffered from ulcer of the leg.

The specific therapy had, thus, in cases in which the thrombosis remained localized to the calf permanently saved the patients from a chronic, painful, more or less severe, disablement.

THE TECHNIQUE OF ADMINISTERING HEPARIN

In most of the Swedish clinics heparin administration is started as follows: 350 to 450 milligrams a day are divided into four intravenous injections which are given at 8:00 a.m., 12:00 m., 4:00 p.m. and 8:00 p.m. or 10:00 p.m. in amounts of 125, 100, 100 and 125 milligrams. On the third day the dose is lowered, e.g. to 300 to 350 milligrams. In case dicoumarol is given on the first day heparin is omitted as soon as an appropriate prothrombin level is reached. The same scheme is followed even in case of an acute pulmonary embolism. The use of dicoumarol alone is not permitted because it has repeatedly been observed that thrombosis in the calf proceeds to the thigh in spite of dicoumarol treatment. In fact heparin treatment has aborted the disease before the full action of dicoumarol

JORPES ANTICOAGULANT THERAPY IN THROMBOSIS

has evolved. Patients are consistently asked to move about in the bed as much as possible even on the second day and early ambulation is routine. Thus the average time in bed in Bauer's series was 4.6 days and in the other Scandinavian series 1 week to 10 days instead of 5 to 6 weeks as found in the series of patients treated conservatively.

can reduce the incidence of thromboembolism. The incidence of thrombosis can be reduced to about 0.6 per cent in surgical clinics as is evident from Table IV.

Even in the Scandinavian series the mortality rate in thrombosis is still about 20 per cent, the same figure as that found at the beginning of this century in the surgical clinics of Germany and Austria as well as at the Mayo Clinic in this country during recent years. Consequently, there is a need for specific therapy.

Treatment now varies under different conditions. In small hospitals where no prothrombin analyses can be made only heparin is used. The time of coagulation of the blood is as a rule not determined. There seems to be a very small risk in using heparin without blood analyses. As to the use of heparin the contraindications seem to be very few. The risk of hemorrhages occurring is minimal. Hemorrhage is to be considered in the prophylactic treatment of postoperative cases but it has proved to be very insignificant in the ordinary treatment of leg thrombosis and pulmonary embolism.

The principles to be applied will at least partly depend upon the prevailing conditions. Venous ligation has in larger surgical units in this country given extraordinarily good results. In clinics where the prothrombin level of the blood can be adequately followed, dicoumarol has been used either alone or in conjunction with heparin. In all smaller hospital units, like that of Baner in Sweden, heparin treatment can be applied successfully. It is in fact to be resorted to in every case of early peripheral leg thrombosis and in acute pulmonary embolism.

OTHER THERAPEUTIC MEASURES

The question arises whether similar results as those reported here also could be obtained by other means, such as through active movements and early getting up from bed. Sympathetic block causing vasodilatation in the leg and surgical ligation of the larger veins. It is evident that exercises under medical supervision and the early getting up of patients

The relative value of the different methods for the treatment of peripheral leg thrombosis or pulmonary embolism will of course become the subject of closer study during the next 5 to 10 years. At present we can confine ourselves to the statement that physiology and biochemistry have given us specific means which are highly effective in the treatment of thrombosis.

THE TREATMENT OF CHRONIC NONTUBERCULOUS PULMONARY ABSCESES BY HIGH VACUUM SUCTION DRAINAGE

HARRY E. NELSON M D Dallas, Texas

DURING the past few years there has been progressive improvement in the management of chronic pulmonary abscesses. Lobectomy or occasional external drainage is now being employed with excellent results. It is felt, however that in some well selected cases equally good results might be obtained by simpler means.

Often simple external drainage will fail and lobectomy despite the excellent results, remains a formidable procedure which may result in the loss of some functional pulmonary tissue which demands much of the time and energy of a skilled thoracic surgeon, an experienced anesthesiologist, and a trained surgical team as well as the services of a blood bank. No time need be spent, therefore, in advancing the desirability of a simpler method of treatment.

The purpose of this brief communication is to describe what may be such a method of treatment for certain carefully selected cases of chronic pulmonary abscess. To date, it has been employed in only 10 cases, but the results in all in which the method has had a fair trial have been so good that it seems justifiable to place the small series on record in the hope that other surgeons may be encouraged to test the method and that a group large enough to be of statistical significance may be accumulated for analysis within a reasonably brief period of time.

The method proposed is an application of the continuous high vacuum suction drainage described by Neville in 1939 for the management of chronic empyema thoracis. He was confronted with a patient slowly wasting away with chronic empyema of 2½ years duration.

Within 4 weeks after thoracostomy and the institution of high vacuum suction drainage, the previously extensive empyema cavity had been reduced to a straight tract the size of the drainage tube, and within 7 months the patient had returned to work and was apparently completely well.

When this method came to my attention shortly after it had been described, it struck me that it might be useful in certain types of pulmonary abscess which in chronicity and other respects could be considered analogous to chronic empyema. The validity of the method as applied to chronic pulmonary abscess seemed enhanced by a careful study of pulmonary lobes resected for this cause. In some of these cases the conclusion seemed warranted that a cure might have been obtained by simpler means, with greater economy of time and personnel, with conservation of pulmonary tissue, and with less risk to the patient.

The term chronic in this connection is used to designate that type of pulmonary abscess which has existed sufficiently long to show roentgenologically a definite fibrous tissue capsule. Not all observers, of course, would agree with this definition but as the basis of selection of cases for high vacuum suction drainage, it is an entirely adequate point of departure. If the zone of surrounding fibroplastic tissue is slight as in the type of abscess which in some quarters might be termed subacute or even acute, the abscess is given the opportunity to heal spontaneously or simple external drainage is employed. If on the other hand a considerable degree of lobar fibrosis and bronchiectasis is present, lobectomy is regarded as indicated.

The selection of cases for this method of treatment rests on still other criteria. The abscess must be single. It must be peripherally

From the Division of Surgery, Southwestern Medical College. Presented in the forum on Fundamental Surgical Problems, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Fig 1 Roentgenogram taken prior to operation revealing a spherical mass peripherally placed in the lower part of the upper lobe and in contact with the parietal pleura.

Fig 2 Lateral projection corresponding to Figure 1 showing the lesion to occupy the posterior part of the upper lobe.

located. A pleural bridge must exist, so that satisfactory external drainage can be instituted without traversing the pleural space. If malignancy is a possibility and if the usual diagnostic measures do not absolutely exclude it, exploratory thoracotomy and biopsy must be carried out. Finally the lesion must be observed sufficiently long to make certain that the cavity is not decreasing in size spontaneously or under conservative methods of treatment. If these various criteria are met, the case is regarded as suitable for high vacuum suction drainage.

The operation is preferably done under intercostal nerve block. If preliminary aspiration reveals the existence of an adequate pleural bridge the lesion is approached directly. If there is doubt regarding or definite evidence against the existence of such a bridge, exploratory thoracotomy is carried out by way of a small strategically placed incision and the site of the skin incision for drainage is determined by the location of the pleural bridge.

If no bridge is found the method of treatment contemplated must be discarded in favor of lobectomy.

The abscess cavity is entered after resection of a small segment of overlying rib and a drainage tube of appropriate size is inserted and made air tight by the use of flanges and sponges. Patent bronchial openings in the walls of the cavity are fulgurated but if this procedure be necessary suction drainage is not instituted until they have closed.

Neville described the machine which he had devised for his patient, but in hospitals equipped with built in suction systems no special machines are necessary. The suction apparatus is set at between 5 and 10 inches of mercury and the level is decreased only if the patient complains of a sense of severe pulling in the chest or if hemorrhage of serious degree occurs. The routine described by Neville is carried out with minor modifications. Thoracoscopic inspections of the cavity are made at weekly intervals and the measurements are

Fig. 3. Roentgenogram taken after operation shows the drainage tube passing through the resected segment of the fifth rib and the decrease in density of the lesion following suction therapy. The abscess cavity previously invisible is now quite apparent.

Fig. 4. At the time this film was taken the tube had been removed although the film indicates that a cavity may still be present. This is due to the peculiar arrangement of the fibrous tissue remaining in the upper lobe. The cavity has been observed fluoroscopically to flatten out against the parietal pleura and become obliterated. This patient has been asymptomatic for over 7 years and bronchograms reveal no abnormalities.

recorded at the same time for comparative purposes.

As soon as the patient is sufficiently improved to leave the hospital, he is instructed in the use of a small suction machine (available on rental from a commercial firm) which is similar to the standard tonsillectomy suction machine but is mechanically superior. It is capable of maintaining high vacuum suction for prolonged periods, with only brief intervals of nonoperation for the purpose of cooling the motor. The patient returns at intervals as necessary for observation until the abscess cavity is obliterated.

In every case in which a patient was treated by this method the clinical course has been the same. Following closure of the fulgurated bronchial orifices, if fulguration has been necessary and the institution of high vacuum suction drainage the size of the abscess cavity decreases rapidly and striking changes occur in the granulation tissue lining it. Previously

pale and edematous, it rapidly assumes a healthy appearance and many new blood vessels are observed. The sites of the bronchial openings gradually disappear and the medial wall of the cavity approaches, and finally flattens out against, the parietal pleura. This important development in the healing process is hindered when the cavity is packed but is encouraged by the suction method of treatment.

In about half of these cases suction was discontinued for periods of as long as 2 weeks, as a control measure. Invariably the diminution in the size of the cavity previously progressed, was halted and was not resumed until suction was reconstituted.

The 10 patients in this series ranged in age from 20 to 65 years, every intervening decade being represented. The duration of illness prior to treatment had ranged from 3 to 18 months. Suction drainage was necessary for

an average of 3 weeks. In no instance in the series did it fail to bring about prompt decrease in the size of the cavity eventual complete obliteration and corresponding improvement in the condition of the patient. No untoward results of any kind have been connected with its use. The earliest of the cases has been followed for a 2 year period and all other patients have been followed for at least a year. During the period of observation there has been no recurrence in any case though, because of the short time interval since treatment, the possibility of recurrence cannot be entirely discounted. Roentgenologic exami-

nation after obliteration of the abscess cavity has revealed in all cases persistence of shadows indicative of residual fibrosis.

Although the present series, as stated, consists of only 10 cases, the results secured seem to justify this preliminary report, chiefly because it is hoped that others will test high vacuum suction drainage in chronic nontuberculous pulmonary abscess and will report their results.

RATE OF GAIN IN STRENGTH IN SUTURED ABDOMINAL WALL WOUNDS

JOHN FAST, M.D. CARLETON NELSON M.D. and CLARENCE DENNIS M.D.,
Minneapolis, Minnesota

IN recent years a great deal of attention has been given to early ambulation following laparotomy. The strength of a wound immediately following the placement of sutures depends primarily on the total number of sutures which have been placed and upon the ability of the tissues to hold the sutures as well as the tensile strength of the suture material employed and the manner of placement of those sutures. A review of the literature on wound healing yields very little reference to the rate of strength gain across incisions through the rectus muscle and fascia following approximation of the muscle and fascia with interrupted silk sutures. In the present study our objective is the determination of the amount of healing at different periods of time by measuring the tensile strength of the healing wound with non-absorbable sutures remaining in place.

According to Howes and Harvey the rate of strength gain in a healing wound resembles the curve of growth in general (4). There are 2 periods in the strength gain of a healing wound, the first, the so-called 'latent period' (2) lasts from 3 to 5 days. In the second period of the curve of normal healing strength increases rapidly and this phase continues until the wound is completely healed. Microscopically this period is associated with the process of fibroplasia (5).

METHODS

For the purpose of this experiment commercially raised healthy white rabbits were employed. These rabbits were maintained throughout the experiment, on a stock rabbit diet consisting of rabbit pellets and water. They were kept on this diet both before and after operation, and no attempt was made to add or subtract any dietary factor which would enhance or hinder the process of wound healing. Also no attempt was made to choose a uniform size, weight, or sex. Both medium and large healthy rabbits were employed.

From the Department of Surgery, University of Minnesota. Supported by a Research Grant from the Graduate School of the University of Minnesota.

Presented in the forum on Fundamental Surgical Problems before The Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Fig. Tensiometer employed for determination of strength of tissues. The strip of tissue to be tested is gripped in two forceps which remain perpendicular to the line of tension. The tension is slowly increased by turning a large spool connected by a wire to one of the forceps on the

tissue. The other forceps is attached by wire to the spring. A rider point is moved over the calibration guide bar by the stretching of the spring, and marks the point of maximum tension. Control tissues repair ruptured midway between the clamps.

The rabbits were anesthetized by the injection of a necessary amount of aqueous sodium pentobarbital into the marginal vein of the ear. Roughly 35 milligrams of the drug were used per kilogram of weight. The hair was removed from the abdomen with barium sulfide and the skin washed thoroughly with water to remove all traces of the chemical. No marked skin reactions were observed from the use of the barium sulfide as a depilatory. Skin sterilization was obtained by the use of Novak's solution (6) and sterilization was maintained by the use of sterile towels as drapes around the operative field. Rubber gloves were not worn during the operation but operations were preceded by a 10 minute scrub with soap and water followed by rinsing in aqueous zephiran solution. Surgical instruments, heat sterilized prior to the first operation of the day were kept in a solution of aqueous zephiran 1:1000 between cases. The No. 000 and No. 0000 black silk (Deknatel) used for closure was autoclaved at 250 degrees for 10 minutes. All suture material was new and none of it was autoclaved more than once.

A midline skin incision roughly 14 centimeters long was made beginning at a point just below the xiphoid process and carried down to the lower midabdomen. This incision exposed the linea alba. At this point the superficial fascia was separated either to the right or to the left of the midline and one an-

terior rectus sheath was exposed. An incision was then made through the midanterior rectus sheath, rectus muscle, posterior rectus sheath, and peritoneum, usually about 1 centimeter from the midline.

The closure of the rectus incision was made by interrupted sutures. No. 000 silk was used in some rabbits, and No. 0000 silk was used in others. The anterior rectus sheath, rectus muscle, posterior rectus sheath, and peritoneum were all included in interrupted through-and-through stitches placed at regular 5 millimeter intervals. The bite included 2 millimeters of tissue on each side, and knots were tied with one square knot just tight enough for apposition without blanching. The skin was closed by means of a continuous suture of black cotton.

The rabbits were studied at varying times during their periods of wound healing. Some were sacrificed immediately and their wounds measured for tensile strength, others were sacrificed at 24 hours, 48 hours, 72 hours, 5, 7, 9, 11, 15, 21 days and 6 weeks. No fewer than 6 rabbits were used for any single period's determinations except 9 days, and as many as 18 rabbits were used for some. In all, a total of 128 rabbits was used in this series, roughly 20 to 24 determinations were made on each rabbit, a total of roughly 2400 separate observations in all.

The rabbits were killed by the intravenous administration of 10 to 15 cubic centimeters

TABLE I.—TENSILE STRENGTH OF SILK SUTURED ABDOMINAL WOUNDS IN RABBITS

Ratio of strength of wound to strength of
previously undisturbed side

✓ R. The σ to transfer strength of the control sides and from
the σ to the σ is very important in the quality test in which
the flow is not uniform and the strength is not being regularly
transferred with irregularity. The width of the strips is
the same as the width of the control sides. The correct for such
cases is to use the width of the control sides. The control sides
are 100 grams and 100 grams per cm. in different that

of air. Immediately after the animal had expired the skin was stripped from the abdomen. Careful note was made at this time of the presence or absence of any serous blood, or purulent accumulation near or on any of the wounds of the rectus muscles, also any gross evidence of stitch infection.

Next the entire abdominal wall was excised and placed on a moist towel to prevent drying. This block of tissue was pinned to a cardboard beneath the towel to prevent the specimen from slipping during the process of sectioning into strips. The tissue was then cut into strips 1 centimeter in width each strip running across the midline through the intact rectus muscle on the opposite side as well. Thus each strip of tissue consisted of a portion of the rectus wound with two silk sutures in place linea alba and the previously undisturbed rectus on the opposite side the entire transverse piece being 1 centimeter in width and about 4 centimeters long. Using a modified suture tying device (1) ten tie strips, three on each side of the midline was tested. The mean tensile strength of the suture portions on each half was divided by the mean tensile strength of the previous undisturbed portion to determine the per cent tensile

WOUND STRENGTH
Per cent of previously undisturbed side

Fig. 2. The tensile strengths of silk-sutured abdominal wound in rabbits at various periods after repair. The smooth curve gives in most instances within 0.6 times the standard deviation from the mean from the average for each time period, and in all cases within the width of the standard deviation from the mean.

Strength of the wound Usually 10 determinations were made on each side of each rabbit. Between 4 and 18 rabbits were tested for each period's determinations. An average of all percentages was taken for all the rabbits tested at a specified period to plot the curve of wound healing.

Where there was any evidence of gross infection or abnormal appearance of the wound the rabbit was not used in the tests. Microscopic sections of all wounds tested were made and studied. Here too, when there was any evidence of infection or variation from normal wound healing the determinations were not included.

Tensiometer. We were unable to find in the literature a description of a tensiometer adequate for our purposes. One was therefore devised on the basis of the general principle employed for the suture testing apparatus.

previously reported by one of us (1). A stout spring is stretched by tension on the strip of tissue to be tested. The rupture tension is recorded by a free rider which remains at the point of maximum tension after rupture has occurred (Fig. 1).

At the conclusion of these experiments a tensiometer of German make was found described in Sandblom's paper (8) on skin healing. It has the added factor of constant rate of increase of tension prior to rupture, and is therefore probably superior to the one we have used.

RESULTS

The first difficulty encountered was wound infection. Routine gross examination of wounds and microscopic examination of one segment of each wound resulted in the discard of 17 animals on this basis and 1 on the basis of hemorrhage into the wound.

It was found possible to construct a smooth curve of strength gain which falls well within the limits of the standard deviations from the mean value for each time period (Fig. 2, Table I).

At the completion of closure the wound with sutures present was 41.9 per cent as strong as the previously undisturbed opposite side. This value dropped very slightly during the next 3 days, and then rose sharply approaching 80 per cent at 15 days and rising significantly no more after that point.

Certain variations in these results were found to attend variations in type of suture material including catgut, and manner of placement. These are the subject of further studies by 2 of us (Carleton Nelson and John Fast) and will be reported in later communications.

CONCLUSIONS

1. The strength at varying periods of the healing wound plus the sutures employed is of paramount interest to the surgeon in the light of the present trend toward early ambulation.
2. In rabbits, the strength of the freshly silk-closed abdominal wall wound is about 40 per cent of the undisturbed opposite side and remains at this value 3 days. Thereafter it rises steeply to about 80 per cent at 2 weeks.
3. In the 6 weeks of observation in rabbits, silk-closed wounds never regained full preoperative strength, remaining at about 80 per cent of that value.

EXPERIMENTS WITH NONIRRITATING GLOVE POWDER

C. MARSHALL LEE, Jr. M.D., F.A.C.S. Asheville, North Carolina, and EDWIN P. LEHMAN
M.D. F.A.C.S. Charlottesville, Virginia

SINCE the introduction of dry glove technique now almost universally employed by surgeons everywhere the powder used on rubber gloves has been under some degree of suspicion. But since any ill effect it might produce was masked by other more obvious factors such as infection, trauma, or suture material it attracted comparatively little attention. The incrimination of lycopodium powder as the causative agent in many granulomatous lesions and intra-abdominal adhesions is now too well known to require detailed review. The historical aspects of this subject have been ably presented by Seelig Verda, and Kidd (13). The use of lycopodium powder was rapidly abandoned in favor of magnesium silicate or talc. This inorganic material was thought to be physiologically inert in contact with living animal tissue and is now generally employed as a dusting powder for surgeons' gloves. With recognition of silicosis as an industrial disease entity some interest was aroused in the possibility that talcum powder might not be entirely innocuous. In 1933 Antopol reported 2 cases of granuloma due to talc—one in the neck and one in the serosa of the appendix. These 2 cases were mentioned in passing in a report on lycopodium granuloma and the possibility was suggested that unrecognized talc granulomas might be quite common. Feinberg reported 2 cases of talc granuloma in 1937 and for the first time employed polarized light both to demonstrate and to identify the crystals responsible for the lesions. He injected small amounts of talc suspended in saline into three mice and produced granulomas, but no adhesions, and warned against the indiscriminate use of talcum powder in the operating room.

Although scattered confirmatory reports (2, 4, 6, 10, 11) appeared in the literature, little attention was paid to them by clinical surgeons and in 1943 a second and quite comprehensive article by German (7) emphasized the danger of granuloma formation but minimized the tendency to form intestinal adhesions. In 40 of 50 unselected patients who were subjected to a second laparotomy German found intra abdominal granulomas which he proved by means of polarized light to be the result of foreign body reaction to talc. Although there was a close parallel between the number of adhesions present and the number of granulomas the adhesions were attributed entirely to col lateral causes. He stated "In the mechanism of the formation of adhesions it is well known that fibrin plays an important part. The inability of silica *per se* to induce an exudation of fibrin would suggest that it is not important in the formation of adhesions. These observations would point to a very efficient mechanism for disposal of talc by the peritoneum."

German based his conclusions on the intra peritoneal injection of a 0.5 per cent saline suspension of talc into mice and on dry powder application in which he used only one test rabbit and one control rabbit, with and without trauma. He produced granulomas, but no adhesions. On this basis he concluded that

Talc *per se* in the abdomen in the absence of injury to the peritoneum is quickly removed from the peritoneal cavity, immobilized and covered with serosal cells, without the formation of an exudate and without adhesions. Adhesions do not develop without some form of traumatization of the peritoneum sufficient to produce exudation of fibrin. Even in the presence of peritoneal trauma and exudation of fibrin the talc plays a secondary rôle, in that it is caught up in the fibrin and is incorporated in the adhesions. Thus the developing granulomas may either add to the bulk and density of the developing adhesions or may

impede the resolution of any adhesions once formed. In this sense it may be said to contribute to the disability produced by adhesions resulting from surgical operations.

It remained for Seelig (12-13) to re-emphasize strongly the danger of talc as an adhesion producing agent. Although mice are notoriously recalcitrant to the production of adhesions, he was able to produce generalized adhesions quite uniformly in a large series (194 mice) in which 2 cubic centimeters of a 5 per cent saline suspension of talc was injected intraperitoneally. He tested some 24 different powders and selected potassium bitartrate as a nonreactive substitute. Later he employed a starch powder which was said to withstand autoclaving fairly well. This represents the first reported use of a starch derivative for this purpose and our studies constitute an extension of Seelig's work with certain modifications in methods and materials.

In a comprehensive and detailed study Lichtman, McDonald, Dixon and Mann have shown that talc is not an inert foreign body. They point out that commercial talcum is a mixture of talc, serpentine, dolomite or tremolite. Talc itself is a hydrous magnesium silicate. The material leached out of a talc crystal is not the same as the parent substance. The degree of hydration of this derivative substance determines its toxicity. For ex-

ample a mole of alpha silicic acid may bind as many as 300 moles of water. The size, shape, and cleavage of a talc particle and its surface energy affect its so called solubility. In the body, alteration of the pH and the presence of protein in tissue fluids alter the size and characteristics of the dispersed aggregates. By means of the now common use of polarized light they conducted an extensive study of the pathogenesis of talc granulomas and adhesions, resulting from dispersed talc particles 0.5 to 10 microns in size.

The greatest barrier to the abandonment of talcum as a glove dusting powder has been the lack of an acceptable replacement for it. Many powders have been studied and the commonest single defect in those which are physiologically safe has been a tendency to gelatinize or agglutinate in the autoclave, thus defeating the primary purpose of the powder, namely to lubricate gloves and hands.

A further barrier to replacement of talcum powder has been a general failure fully to appreciate its danger. In most hospitals surgeons do not even take the precaution of washing the powder from their gloves before operating.

The purpose of our study was to verify the increasing evidence that talcum powder is a dangerous agent in human surgery and to evaluate certain proposed replacements for it.

EXPERIMENTAL STUDIES

Physical properties. Preliminary selective studies were made on the physical properties of ten powders, with commercial talc as the control.

The powders (Table I) used in this study were made available to us by the Department of Clinical Research, Ethicon Suture Laboratories, Division of Johnson and Johnson, New Brunswick, New Jersey. The first four powders have already been tried out by other investigators (7-11) and were included for comparative purposes. The last four powders, designated 100, 101, 107 and 108 are derived from corn starch which has been treated by physical and chemical means to prevent gelatinization in the autoclave. These four powders differ substantially only in degree of treatment, except that numbers 107 and 108 have

had a special chemical treatment to improve their lubricating value. The identity of the remaining powders in Table I is self-evident.

The fineness and flow and dusting qualities of the raw powders were arbitrarily classified by gross estimation from + to +++++ the latter representing the greatest freedom of flow and ease of distribution in dusting gloves and hands. Samples of each were then autoclaved under 15 pounds of pressure for 15 minutes and retested. The results are shown in Table I.

Examination of these results shows that powders 100 and 101 were about comparable to talc and that powders 107 and 108 and tantalum oxide were superior with respect to physical qualities after autoclaving. No experiments on tissue tolerance were conducted with the group of powders showing inferior physical qualities. Powder 107 was also eliminated because since No. 108 was known to represent a further refinement of it detailed study became an unnecessary duplication. Tissue tolerance studies were therefore conducted on powders 100, 101, 103, A (tantalum oxide) and 108, with talcum (104) as a control.

Method of testing peritoneal reaction. Dogs were selected as the test animals because actual operating room conditions could be closely approximated and because the peritoneal reactions of dogs more nearly approach human reactions than do those of mice, rats, guinea pigs, or rabbits which have been used in studies heretofore reported by others. In a further effort to duplicate operating room conditions, dry powder was used in open operation rather than by injection in a saline suspension.

In every operation the abdomen was opened through a standard rectus incision. Rigid aseptic technique was employed throughout, except that before beginning the operation both operator and assistant washed their gloves thoroughly under running tap water. In every operation the small bowel was run from Treitz's ligament to the ileocecal valve. When a powder was being tested it was dusted as evenly as possible over the bowel and both mesenteric surfaces as the bowel was run. When the last loop had been banded or treated the abdominal wound was closed in layers with silk.

TABLE II.

Equivalents 1 washing from operating room gloves	Weight in grams	Volume in teaspoon measures
2 pairs	0.20	1/4
4 pairs	53	1/4
8 pairs	1.024	1/4
6 pairs	2.01	1

After an interval of 3 weeks each dog was reopened the same technique being used and explored for adhesions. When few adhesions were found a careful count of them was made after the method of Lehman and Boys (13). When adhesions were too numerous to count they were designated +++ or +++++ denoting generalized massive adhesions.

Quantity of test powder. In order to arrive at a suitable quantity of powder for test purposes 4 pairs of gloves were drawn from the ready supply in the operating rooms of the University of Virginia Hospital. The outer surfaces of these gloves were washed as thoroughly as possible under a single washing with a fixed quantity of water.¹ The water was then evaporated and the residual powder was found to weigh 0.5262 gram. This was taken as the maximum amount of powder with which the peritoneal cavity might be contaminated by an operating team of four persons, if only one pair of gloves were worn by each and if none of the gloves was punctured.

Since the powders to be studied were of different specific gravities a volumetric measure was considered better for comparative purposes. A set of kitchen teaspoon measures was employed and approximate values were obtained for talc (Table II).

One-half teaspoonful represents the amount of talc from 8 pairs of gloves. On this basis in order to make the tests sufficiently rigorous this amount was selected as the dose to be dusted over the peritoneum of dogs. Certain exceptions to this dosage will be noted under results.

Bacterial studies. Although it had already been shown that the physical properties of powder 108 were not impaired by autoclaving it seemed desirable to establish that this

¹It is of interest that when these washed gloves were air-dried they were still abundantly covered with a fine coating of powder.

Fig. 1. Small bowel of dog treated with talcum powder. The bowel and mesentery have been removed and laid over the end of bucket. Adhesions are so numerous and dense that the cohesed mass hangs together like a cap.

powder (which will be shown to have a high order of tissue tolerance) could in fact be effectively sterilized.

Through the courtesy of Dr Frank Meloney's laboratory at Presbyterian Hospital, New York, some spore threads were obtained of a highly heat resistant strain of *Bacillus subtilis*. This strain when the test tube is completely surrounded by the water will withstand boiling for 20 minutes.

A sample of powder 108 as received was autoclaved for 15 minutes at 15 pounds pressure. Culture from this sample was sterile.

A second sample was contaminated with heat resistant *Bacillus subtilis* spores and then cultured without autoclaving. *Bacillus subtilis* was readily cultured from the sample.

TABLE III.—CONTROL STUDIES—NO POWDER AND TALCUM POWDER

Type of powder	Amount of powder	Equivalent in glove washings	Number of dogs	Average number of adhesions	Greatest number of adhesions	Smallest number of adhesions
None	None	None				
Talcum Powder	3/4 Tsp	8 Pts.		++++	++++	++++
	3/4 Tsp	4 Pts.	5	++++	++++	++++
	1/2 Tsp	Pt.		+++	+++	+++

Fig. 3. Section under low power through an adhesion between two loops of bowel.

A third sample was similarly contaminated and then cultured after autoclaving. Culture from this sample was sterile.

RESULTS

Controls (Table III). No adhesions resulted when no powder was used. When talcum was used dense generalized adhesions were formed. Even when the dose of test powder was reduced to 1/2 teaspoonful or roughly the washings from one pair of gloves the result was the same.

These dogs were sacrificed and at autopsy the small bowel was removed *en bloc* and formed one cohesive conglutinate mass which, when draped over the end of a bucket, sat on it like a cap (Fig. 1). The small spots of agglutinated talc were readily visible in gross under the adhesions (Fig. 2 (frontispiece)). Microscopic sections taken through sample adhesions showed the talc embedded under the adhesions against the serosa (Figs. 3 and 4). Under polarized light the identity of this material was evident (Figs. 5 and 6). The celiac and superior mesenteric nodes were greatly enlarged. Sections of these were taken to de-

Fig. 4. Higher magnification of the area indicated by the arrow in Figure 3. This shows the inflammatory reaction and the numerous foreign body giant cells.

Fig. 5. The same area as shown in Figure 4, under polarized light with partial rotation of the prisms. This brings out the larger talc particles.

termine whether or not there had been any phagocytosis of the talc with deposit in the regional nodes. Under ordinary light these sections showed only the usual inflammatory lymphoid hyperplasia. Under polarized light exhaustive study showed only an occasional birefringent particle—an average of one to three a section.

Experiments (Table IV) Tantalum oxide produced as extensive adhesions as did talc. Further work on this powder was abandoned.

The results with powders 100 and 101 were encouraging and in the case of the latter suf-

ficiently so to suggest testing the effect of an increased dosage. Two dogs were treated with a full teaspoonful of powder 101 equivalent to washings from 16 pairs of gloves. It is of interest that each of these dogs had been used in a previous series and the increased dose had been put in when they showed no adhesions after the first test. One dog showed no

TABLE IV — EXPERIMENTAL STUDIES—TEST POWDERS

Type of powder	Amount of powder	Equivalent in glove washings	Number of dogs	Average number of adhesions	Greatest number of adhesions	Smallest number of adhesions
Talc-lens oxide	¼ tsp.	8 pra.	3	++++	++++	++++
Starch No. 100	¼ tsp.	8 pra.	5	5.7	13 (++++)*	0 (1 dog)
Starch No. 01	¼ tsp.	8 pra.	2	4	8	0 (2 dogs)
Starch No. 101	1 tsp.	16 pra.	2	5	5	0
Starch No. 106	¼ tsp.	8 pra.	10		0	0

*One dog had an infected laparotomy wound and showed +++ adhesions. Because of this extraneous factor the average and greatest number of adhesions is taken from the remaining four dogs.

Fig. 6. The same area as in Figures 4 and 5. Here the prisms have been completely rotated blotting out all but the doubly refractive talc particles.

adhesions at his third laparotomy and the other showed only five. Since powder 108 was known to represent a further refinement in processing and since its physical properties were superior the next major series was conducted with this powder. In every case when the dog was opened after 3 weeks not a trace of powder was to be found nor was there a single adhesion present. The bowel when removed *en bloc* was as clean and healthy as if it had never been touched (Fig. 5). These striking results indicate the superiority of powder 108 over every other powder tested and are as good as the controls without powder.

CLINICAL EVALUATION

By arrangement with the superintendent of a private hospital in this city powder 108 was installed in the operating room in place of talcum without the prior knowledge of the surgeons working there. The operating room supervisor was asked to take note of any comment they might spontaneously make.

With only one exception every surgeon commented favorably having noticed the improvement in physical quality over the powder previously in use and asked what the new powder was. The single exception made no comment at all favorable or unfavorable and apparently did not notice the change.

In the course of this trial use only one unfavorable feature was observed. It happens that in this particular hospital glove powder is put up in aluminum salt shakers and used throughout the course of a day's operating schedule. Frequently these shakers are emptied in one day and are reautoclaved and used again the next day. It was noted that while the physical properties of the powder remained unimpaired through one or at most two autoclavings there was some tendency to clump after the third such sterilization. After the fourth or fifth although the clumps were readily shaken out and fine dusting powder could be obtained from the can many residual lumps were left.

This single disadvantage seems trivial in comparison with the many advantages derived from the use of this powder and is easily obviated either by using smaller shakers or by employing the widely used technique of put-

ting up the dusting powder in individual packages with each pair of gloves.

DISCUSSION

It has been shown in our control studies that the atraumatic, aseptic manipulation and handling of the small bowel does not produce adhesions in healthy dogs.

When dry talcum powder is dusted over the serosal surfaces massive dense and uncountable adhesions were produced wherever the talc came in contact with the tissues. This indicates that neither trauma nor infection are required in the presence of talc to produce adhesions and the powder alone must here be held responsible. This is in direct contrast to the observations reported by German.

Furthermore our study of the regional lymph nodes indicates that at least after 3 weeks any effort on the part of the body to remove the powder via the lymphatics has been unsuccessful.

Our observations on the test powders indicate that powder 108 is completely absorbed from the peritoneum without any demonstrated inflammatory reaction and that it produces no adhesions whatever.

The fate of this powder does not offer any great pharmacological problem (5). Since it is a corn starch powder it is simply taken up by the peritoneum and metabolized like any ingested starch. Its advantage over raw starch and other treated starches is that its dusting, lubricating and flow qualities are not adversely affected by autoclaving. Its superiority over talcum powder, tantalum oxide or any other mineral, metallic or nonmetabolized powder is obvious.

MacQuiddy, who has investigated the sensitizing propensities of this substance both in human patients and in animals, has failed to demonstrate under experimental conditions any sensitizing or anaphylactogenic properties. However subcutaneous tissue sections obtained by MacQuiddy indicated that in some instances at least complete absorption of the powder had not occurred at the end of 56 days. In such cases, relatively large compact masses (up to 200 mgm.) had been embedded and under such circumstances absorption might be expected to be slow and

difficult. MacQuiddy's studies are being continued and will be reported in detail at a later date

CONCLUSIONS

1 Further evidence is presented that talc is a deleterious substance in living tissue, that it produces a violent peritoneal reaction and dense adhesions and that its use as glove dusting powder is dangerous.

2 A commercially prepared dusting powder is shown experimentally to have

a. Excellent physical qualities of flow and fineness, unaffected by autoclaving

b. Complete absorption by the peritoneum without inflammatory reaction and without the formation of adhesions

c. Complete sterility under standard autoclaving procedure after known contamination with spores of a heat resistant organism.

3 A brief clinical trial of this powder has been entirely satisfactory

EXPERIMENTAL IMPLANTATION OF THE COMMON BILE DUCT INTO THE INTESTINE

FREDERICK M BINKLEY M.D., ROBERT PALMER, M.D., and
H J McCORLIE, M.D., F.A.C.S. San Francisco, California

CLINICAL and experimental surgical procedures in which the bile duct is implanted into the intestinal tract have been employed with increasing frequency in recent years. It is desirable that biliary intestinal anastomosis be done in such a manner as to prevent leakage of bile into the peritoneal cavity in the early postoperative period and to avert the later postoperative complication of cholangitis which often is associated with stricture at the site of anastomosis, stasis and infection of bile, and probably with reflux of intestinal contents into the biliary duct system.

In consideration of these points several types of experimental implantation of the common bile duct into the intestine of dogs were performed in an attempt to develop an efficient, simple procedure.

The experiments were divided into four main groups

1 *Simple implantation* Choledochoduodenostomy was done in 13 dogs, 8 of which had a normal common bile duct. In the remaining 5 animals the common bile ducts were ligated at a preliminary operation. Two or 3 weeks later these animals were reoperated upon and the dilated common bile ducts were implanted into the duodenum.

The technique of implantation of the bile duct into the duodenum is illustrated in Figure 1. After the bile duct is ligated and dissected free a single row of interrupted cotton sutures is placed posteriorly approximating the duodenum and the posterior wall of the common duct at a distance of 3 to 5 millimeters from the free end of the duct. The posterior row is tied under direct vision, in

order to insure accurate serosa-to-serosa approximation. Two incisions are then made in the duodenum one just anterior to the suture line and with a curved hemostat which is passed through the two incisions, the common duct is drawn into the lumen of the duodenum. An anterior row of interrupted fine cotton sutures is placed completing the serosa-to-serosa anastomosis. The ligature is cut from the distal end of the duct, leaving a free end from 2 to 4 millimeters in length extending into the lumen of the duodenum. The second incision is closed with 1 or 2 interrupted cotton sutures.

In none of these animals was there evidence of leakage of bile from the anastomosis in the early postoperative period. The postoperative course was not remarkable except for the urinary findings. In most animals daily urinalysis revealed the presence of bile during the early postoperative period but the urine invariably was free of bile by the 10th postoperative day. In order to determine the cause of the transient jaundice 3 animals were sacrificed on the 5th postoperative day. In these animals the common bile ducts were found to be somewhat dilated. There was considerable edema at the site of anastomosis and in the surrounding duodenum. In all cases bile flowed spontaneously into the duodenum.

The remaining 10 animals were sacrificed from 34 to 338 days after the choledochoduodenal anastomosis (Table I). In these animals the anastomosis was found to be well

healed and appeared to be functioning satisfactorily. There was no evidence of stenosis. The mucosa of the common duct appeared to be continuous with the duodenal mucosa and the orifice usually lay between mucosal folds. Histological sections showed the ductal and duodenal mucosa to be directly continuous, and several histological sections revealed elevation of the duodenal mucosa about the stoma, forming a papilla like structure. There was a minimal fibroblastic response and no evidence of chronic inflammation (Fig. 2). X ray studies failed to demonstrate regurgitation of barium or free air into the extra hepatic biliary passages (Fig. 3).

¹Causes of death, peritonitis, 1; cholangitis.

Fig. 3 Roentgenogram following simple implantation. Gastrointestinal series consistently failed to demonstrate regurgitation of barium or free air into biliary passages.

There were 3 deaths in this group. Two were caused by an overdose of sodium pentobarbital used for anesthesia. One animal died with peritonitis on the 15th postoperative day but there was no apparent leakage of bile from the anastomosis. The origin of peritonitis in this animal probably was contamination with intestinal flora at the time of operation.

3 Simple implantation into blind limb of jejunum. In the second group of 5 animals the common duct was implanted into a blind limb of jejunum (the Roux arm principle being utilized) the same method being used as described for the first group of animals (Fig. 4). In dogs satisfactory fixation of the blind jejunal limb was difficult to obtain and the anastomoses were unavoidably under considerable tension. In 3 of the 5 animals results were satisfactory, and the findings were similar to those described in the first group (Table II). There were 2 deaths. One animal died on the 3rd postoperative day with diffuse peritonitis;

Fig. 4. Simple Implantation into blind limb of jejunum. A, Simple implantation of duct. B, Completed procedure showing implantation into blind limb and end-to-side jejunal anastomosis.

the anastomosis was not healed and there probably was leakage of bile into the peritoneal cavity. The other animal died with acute cholangitis on the 5th postoperative day. The anastomosis was found to be healing satisfactorily with no leakage of bile. The bile ducts were filled with thick, mucopurulent exudate.

3. *Anastomosis using mechanical support*
In a group of 5 animals a dilated (previously ligated) common bile duct was anastomosed to the duodenum over a mechanical support (Fig. 5).

In 2 animals the anastomosis was done over a rubber catheter and in 3 a flanged tantalum

metal tube was used. In the cases in which a rubber catheter was used, one dog was sacrificed on the 10th, and one on the 44th postoperative day (Table III). The anastomoses were well healed and appeared to be functioning.

ing satisfactorily. In one animal the duct wall was thickened and there were numerous adhesions and an increased amount of scarring about the anastomosis. Histological examination revealed a marked increase in connective tissue reaction and inflammatory response when compared with similar sections from implantations in groups I and II (Fig. 6). Two of the 3 animals in which a tantalum tube was used died, one on the 12th and one on the 30th postoperative day. The former was found to have peritonitis resulting from a perforation of one of numerous liver abscesses, and the latter died with pneumonia. In both animals the anastomoses were well healed and appeared to be functioning satisfactorily and the tantalum

tubes had remained in their original position. The third animal was sacrificed on the 20th postoperative day at which time the tube was found to have passed from the site of anastomosis through the intestinal tract. The anastomosis was functioning satisfactorily. However the duct wall was thickened, and histological sections demonstrated an increased amount of connective tissue about the anastomosis with a moderate inflammatory reaction.

4. *Anastomosis using reinforced fascial tube.* In 3 animals the common bile duct was divided at its junction with the duodenum. The defect was replaced by a tube of rat fascia reinforced with a fine tantalum wire mesh. At a preliminary operation a rectum

Fig 6 Photomicrograph of area adjacent to anastomosis performed over rubber catheter demonstrating surrounding connective tissue reaction.

lar flap of rectus sheath was dissected free and folded back over a square of tantalum mesh placed upon the anterior surface of the rectus abdominis sheath and sutured into position (Fig 7). In this manner the sheet of tantalum mesh was covered on its anterior surface by the flap of fascia and on its posterior surface by the anterior wall of the rectus sheath. Two to 3 weeks later this double thickness of fascia, reinforced with tantalum mesh, was excised and fashioned into a tube, which was then anastomosed at one end to a dilated common duct, and at the other end to the duodenum. The anastomosis was performed about a rubber catheter which was left extending into the duodenum and portions of omentum were brought about the anastomosis (Fig 8).

These 3 animals were sacrificed at intervals varying from 119 to 251 days postoperatively (Table IV). At necropsy the anastomoses were found to be surrounded by abundant

Fig 7 Construction of fascial flap reinforced with tantalum mesh. Flap of rectus abdominis sheath turned back over square of tantalum mesh and sutured into position.

vascular adhesions. In all 3 animals the anastomoses were patent and appeared to be functioning; however the extrahepatic biliary system was distinctly dilated. The rubber catheters were noted to have passed into the gastrointestinal tract. The tantalum mesh tube protruded into the lumen of the intestine for a distance of 2 to 3 millimeters and was almost entirely covered with duodenal mucosa. The tubes on being opened were found to be almost completely lined with mucosa, however, there were spotty areas through which the tantalum mesh was visible. A relatively thick fibrous wall surrounded the tube which

apparently was not constricted due to the presence of the tantalum mesh.

SUMMARY

1. A simple type of biliary intestinal anastomosis has been done in 18 experimental animals. It may be done rapidly and has given good functional results with minimum inflammatory reaction at the site of anastomosis.

2. Anastomoses employing a rubber or metal tube have been done in 5 experimental animals and these anastomoses invariably have exhibited evidence of considerable inflammatory reaction, scarring and stenosis.

3. An experimental method for the replacement of a defect in the common duct of

animals by a graft of fascia reinforced by tantalum wire mesh is described.

4. It appears desirable to use the simplest possible type of anastomosis (as described in group I) in situations where a sufficient length of the common duct remains to permit direct implantation of it into the duodenum. Use of the Roux arm principle may not be required in all instances, and might be limited to situations in which the presence or possibility of cholangitis is a factor.

5. The use of metal or rubber tubes for mechanical support in choledochointestinal anastomosis should be avoided if possible because of their tendency to produce marked scar tissue reaction with stenosis. However it

is acknowledged that there are many situations where such support is essential. In such instances temporary support with a very soft rubber tube appears preferable to more permanent support with rigid metal tubes

PRINCIPLES INVOLVED IN SURGICAL THERAPY OF 'ENCAPSULATED' FIBROSARCOMA OF SOFT TISSUES

WALTER W. CARROLL, M.D., Chicago Illinois

IT is an established fact that success in the treatment of any malignant disease depends to a great extent upon a knowledge of its origin and course. This means that the institution of adequate surgical measures based on this knowledge is just as important as the early recognition of the presence of the malignancy. Even though it is the pathologist's responsibility in the average instance to make the actual diagnosis of malignancy when the surgeon is in doubt, it is the surgeon who has undertaken the responsibility to effect a cure. Having undertaken this responsibility it seems logical that he should be expected to possess as complete a knowledge as is practical concerning the pathological entity at hand. When this pathological entity happens to be a sharply delimited tumor found arising from the soft tissues of the body—that is, from the subcutaneous tissue, muscle or intermuscular fascial planes, the gross appearance of this tumor may lead to the impression of a relatively benign process before the pathologist has had an opportunity to declare himself. It is not too unusual that the same impression may be common to both individuals even after using the time saving device of frozen section tech-

nique for histological study with the result that both are temporarily lulled into a false sense of security. Under such circumstances the definitive surgical extirpation results in a simple enucleation of an apparently encapsulated tumor from its bed of areolar tissue. The postoperative clinical impression in such instances agrees with the preoperative diagnosis of perhaps a fibroma until the permanent sections are examined by the pathologist. If the final diagnosis happens to be 'fibrosarcoma of low grade malignancy, the surgeon is faced with the problem of considering the original surgery as being adequate or of choosing a waiting game. Since tumors spread in the human body only by actual dissemination of viable cells or are manifest in more than one part of an area through a multicentric origin the correct decision in this instance will be dependent upon an accurate and full knowledge of the disease process.

PATHOLOGY

The histological studies of the last few decades have made considerable progress in distinguishing among the various tumors once collectively known as fibrosarcoma. In the course of this differentiation an expected amount of controversy has taken place among pathologists, out of which has arisen a fuller knowledge of the growth characteristics of

From Division of Surgery Northwestern University Medical School

Fig. 1. Three examples of fibrosarcoma each of which presents a well defined fibrous capsule despite the variation

in cellular structure of tumor a, highly cellular type; b, fibrous type c, fibromyxomatous type.

these neoplasms. Many forms of spindle-cell sarcoma now prove on closer investigation to belong to groups of tumors arising from nerve structures, muscle fat or synovial tissue. In other words, it now appears that practically all of the sarcomas of the soft parts are derived from specialized tissue cells and not from the supporting fibroblasts. The fascial sarcomas of Virchow⁷ thus remain as one of the few pure forms of fibroblastic sarcoma even though modified by lipomatous or myxomatous degeneration whereas an excellent example of this recent clarification is represented by the synovial sarcoma group. The synovial tissues are generally agreed to have arisen from mesodermal tissue but they normally are composed of an endothelial layer and an outer fibrous layer. The tumors arising from this tissue thus fall into two microscopic types. The first are those arising from the inner layer and are more epithelioid in character while the second are those arising from the outer layer and are usually indistinguishable from the common fibrosarcoma. On the other hand, all gradations of specialized fibroblastic tumor formation now considered as of neural origin may be obtained by a complete study of the pathological possibilities found in von Reck-

linghausen's disease with its significant incidence of malignant degeneration. Such a study reveals that the solitary neurofibroma, the neurinoma and the neurogenic sarcoma all arise from the cells of the sheath of Schwann, that is, from the connective tissue coverings of peripheral and central nerves.

Despite this microscopic differentiation all of the malignant tumors here mentioned manifest sufficiently similar gross characteristics to warrant saying that with few exceptions they present the same common problem to the surgeon. Since they present this common problem we feel justified in discussing them under the common heading of encapsulated fibrosarcoma of the soft tissues.

Most fibrosarcomas arising from soft tissues (except those of retroperitoneal and intraperitoneal origin) usually stem from subcutaneous or intermuscular fascial tissues and even though somewhat low in general incidence their gross appearance of apparent encapsulation is known to surgeons (Fig. 1). It is not uncommon to find them densely adherent to tendinous aponeuroses, thus frequently seeming to be the apparent point of origin. We have noticed that these tumors frequently encompass an occasional nerve trunk of moder-

ate size along with the accompanying blood vessel, but whether this could be considered as a demonstration of nerve origin is difficult to state without histological study. The fibrosarcoma and the synovium have in our experience been single tumors sharply outlined from the surrounding tissues, growing expansively and conforming in outline to the area in which they lie. The neurosarcoma on the other hand may be of unicentric or multicentric origin presenting the same encapsulated or circumscribed appearance. When multiple the localized nodules arising from different parts of the same nerve may fuse with one another so that adjacent nerves running in fascia or muscle may become incorporated in the tumor process in such a manner as to give rise to a false impression of infiltration. When nerves are involved primarily or secondarily there is remarkable preservation of function.

There is no one characteristic gross appearance of these tumors as regards color, consistency or size since these qualities depend entirely on the relative cellular or fibrous content as well as on the presence of internal hemorrhage, necrosis or myxomatous change which in turn may be dependent upon the primary rate of growth of the tumor. Ulceration is usually a very late finding unless the tumor growth is of such unusual rapidity that it outstrips its own blood supply.

RECURRENCES

It has often been stated by way of definition that fibrosarcoma is a tumor arising from connective tissue characterized by a tendency to recur after excision. Taylor and Nathanson recently reviewed 246 cases covering a period of 25 years. Of this group 62 per cent represented recurrences when first requesting their treatment and of the remaining 97 primary cases local control of the disease was effected in only half the patients. One feels that recurrence or persistence of the disease has become an accepted fact when discussing this type of tumor. It is this tendency toward local recurrences that has limited surgical effectiveness in the therapy of the disease. Were this controlled then an increasing number of patients would be salvaged before the well known blood borne fatal metastasis takes place.

Fig. 2. Fibromyxosarcoma presenting a well defined capsule with attachment to nearby muscle due to tumor cell permeation resulting in partial destruction of the capsule.

Study has shown that in general there are four different microscopic mechanisms, any one two three or four of which may be instrumental in the production of the recurrence. The first and probably most common, mechanism is that of extension of the tumor through its capsule with quite minor involvement of a nearby structure. This is far more obvious to the microscopist than to the surgeon. Although this may be overlooked in the gross specimen it may be noted on careful examination as a point of minor adherence to nearby muscle or it may occur at the apparent point of tumor origin (Fig. 2). In general these tumors grow in the direction of least pressure but despite this advantage to the host, the point of origin or any other point of attachment may present areas in which the tumor has penetrated the capsule, even dissolving it at times to invade the surrounding tissue with the capsule appearing grossly intact (Fig. 3). A pseudocapsule may even form to confuse the gross picture, there being a layer of fibrous tissue thrown up in front of the advancing tumor. Such permeation of tumor cells produces a focus which if left *in situ* will be a nidus for local recurrence.

The second mechanism pertains to the factor of lymphatic spread. This is a neglected subject because lymph node involvement typically occurs late in the course of the disease, although in 1926 Hertzler reported a patient with early involvement. It has been noted as high as 8 per cent in a series of 256 cases.

Fig. 3. a, left, Penetration of fibrosarcoma through its own capsule. b, The spread of cells at the apparent

point where the tumor had its origin from the Brown pointoma.

Long duration large size of the primary tumor local recurrence after excision and ulceration are prominent findings in proven instances of lymphatic metastasis. There is no doubt but that the tumor is slow to reach the larger lymphatic regional collecting depots, but the fact that such does occur must make one realize that involvement of lymphatic channels in the areolar tissue about the tumor at the time of excision is a potential hazard for recurrence. Under such circumstances local as well as distant spread of the tumor becomes more likely during the surgical procedure since many new tissue spaces are laid open to the tumor cells.

The third mechanism concerns the concept of multicentric origin of some of the tumors. This follows from the original observations made by Geschickter (3, 4) and by Stewart and Copeland. Working with neurogenic sarcoma they have noted the frequent development of a tumor after surgery higher up in the nerve trunk. Geschickter concluded that this represented an extension from the original tumor along the perineural lymphatic spaces. In the same manner he implicated the perivascular lymphatics of large vessels which were connected with the main tumor mass. On

the other hand Stewart and Copeland have considered such a neoplasm to be an independent new growth arising in the condensed segment of the same nerve, thus attributing a certain tendency toward malignant degeneration to the nerve structures. In studying the malignant changes in 466 patients with von Recklinghausen's disease, Hosoi has shed light on the problem by stating:

In résumé malignant transformation takes place in about 13 per cent of all cases of von Recklinghausen's disease. When this happens, the tumor grows rapidly and tends to recur locally even after repeated operative measures. In some cases the mere extirpation of a malignant tumor or even a benign one appears to stimulate another neurofibroma distantly located to undergo sarcomatous transformation.

The accompanying photomicrographs present an excellent example of multicentric origin of malignant neurinoma arising within the intermuscular fascial planes of the erector spinae muscle group (Fig. 4). The differential identification here lies between a lymphatic metastatic nodule lying in the soft areolar tissue surrounding the primary encapsulated tumor and a second primary neoplasm arising in a nearby branch of the same nerve from which arose the original neurinoma. Close micro-

Fig. 4. a, left, Second primary malignant neurinoma found in areolar tissue surrounding an encapsulated neurinoma of the back b Higher magnification shows the

mimicry of structure including the slight fibrous capsule. The tumor apparently did not reach within a lymphatic channel.

scopic study makes the latter opinion the more tenable.

The fourth mechanism concerns the now well substantiated phenomenon of autoinoculation or implantation at the time of surgery due to spillage of tumor cells into the wound. The experience of Harrell and Volk is cited in this regard. These men reported an accidental autogenous transplantation of an ulcerated fibrosarcoma of the heel to the left thigh during the application of a pedicle skin graft. This was explained as due either to direct extension of the tumor through the graft or by accidental contamination of the incision at the donor site with tumor cells. The experience of Greene in successfully transplanting human fibrosarcoma to the anterior chamber of the eyes of guinea pigs and carrying it by serial transfer through 14 generations adds further weight to this concept.

TREATMENT

Before considering the application of these observations as they might be related to therapy it is of interest first to note the report of Meyerding, Broders and Hargrave covering a 20 year span in which they recorded a 3 year survival rate of 21 per cent in 132 patients afflicted with fibrosarcoma. Since it is now generally agreed that radiation therapy is of little value (1, 12) the obvious conclusion to be drawn from such a pessimistic report as well as our own experience is that the primary surgical attack on these tumors appears to be

inadequate in many instances. For these tumors located in the extremities one might easily conclude that the percentage of cures could be increased by routine amputation but closer examination of a large series of cases reveals that this would result in an unnecessarily large number of amputees without materially lowering the death rate. Thus Meyerding and his co-workers reported that of 28 cured patients in their series only 6 had amputations performed. There is no doubt but that amputation is absolutely mandatory when complete excision is impossible, when deep nerves or vascular trunks appear to be involved or when recurrence has taken place for the first or second time. Even in this last mentioned group where recurrence has taken place, Meyerding reports but five cures in 34 instances where amputation was performed in the absence of demonstrable metastases. We realize that proper evaluation of available statistics on amputation for these tumors is difficult because of the previous inaccurate histological differentiation and also since this maneuver usually has been reserved for the advanced cases, but nevertheless the procedure does not seem to fit all the requirements for the patient requesting primary care.

The answer to this low rate of cure seems to lie in the performance of a more complete local excision at the time of the first surgery. In a negative way this means that the tumor should not merely be shelled out of its connective tissue bed. In a positive way this

means that the tumor and its areolar tissue bed plus any attached muscle, nerve, or blood vessel should be excised *en masse*. Blunt dissection here is not the answer. In reviewing the operative reports concerning the removal of some of these tumors, we have noted that the tumor frequently was shelled from its bed down to an apparent point of origin or at least to a point of attachment from which it was cut free with a scalpel. Because of the lymph drainage within a muscle, it is felt that partial excision of muscle may be inadequate when a muscle belly appears to be invaded. In such instances our experience would lead us to suggest that complete extirpation of the muscle or group of muscles is far superior to a recurrence. Section of nerve trunks and ligation of vascular highways should best be performed as far as possible from the tumor. If involvement of these structures presents insufficient indication for amputation then the least we can advise is wide excision and restoration of nerve continuity with fresh autogenous or homologous grafts. The logic of such a procedure has been clearly demonstrated (2). With the more prevalent ability in skin grafting there seems to be no excuse for allowing any possibility of recurrence by cutting too close to the tumor when excising overlying skin.

APPLICATION OF SURGICAL EXCISION

From the practical standpoint these generalities, if accepted, must be reduced to terms of procedure for the individual patient. In other words some consideration must be made concerning the incision to be used as well as the part to be played by the pathologist if needed in establishing the diagnosis. These steps must be carried out with sufficient ease and safety to allow for the most efficient surgical extirpation possible. Our feeling at this time is that most tumors found in the areas mentioned eventually are proved to be malignant following microscopic study. Very few instances of purely benign tumors can be found among such a group except for the fibromas with their characteristically long history and small size and the lipoma which is quite easily identified. Willson found that 90 per cent of 111 specimens of fibrosarcoma measured over 5 centimeters in greatest diam-

eter while the same percentage of fibromas measured under 3 centimeters. Such information may be helpful but not unless correlated with duration and rate of growth. Certainly any small subcutaneous nodule which has persisted for years and which suddenly begins to grow rather rapidly will be suspected of malignant change before it reaches the critical size of 5 centimeters.

If the diagnosis is obvious a more vigorous attack can be planned at the earliest phase of the surgical intervention. There is no doubt but that the element of surgical judgment is prominent in such a matter and for the sake of clarity it is logical to liken this problem to that of breast carcinoma. In many instances the experienced surgeon can with the fullest justification proceed with his radical mastectomy without the aid of a frozen section because to him the pathological diagnosis is quite evident while in other instances he will rely upon the microscope following a local excision before going on with the more radical procedure. Unfortunately the pathologist finds himself at a disadvantage with the frozen section technique when attempting to diagnose some of these tumors without the use of special stains. Theoretically this very practical procedure loses some of its utility but this does not mean that it should be omitted from our armamentarium when we are in doubt, for it can establish in a general way the degree of malignancy that an individual tumor may possess. By this we mean that a "mad dog" type of tumor can be differentiated from a "sleeping dog" type irrespective of the cellular origin. The relative proportion of cells to fibrillar intercellular substance is probably the best single criterion for estimating the degree of malignancy in these tumors.

SUMMARY

The high mortality rate in patients afflicted with fibrosarcoma presents a severe challenge to the surgeon. Some of these patients probably never will be cured but many can be salvaged by preventing fatal blood-borne metastasis. This form of metastasis appears to be related to the incidence of local recurrence more than to the incidence of the disease. The local extirpation of the disease thus becomes

of paramount importance. Since the tumor frequently occurs in the extremities the question of amputation also must be considered among the methods of obtaining local control of the disease. At the present time we feel reluctant to advise amputation when a satisfactory local excision can be first achieved but on the other hand if a careful evaluation of the speed of growth the size location and histological nature of the tumor would warrant it amputation should be carried out as the procedure of choice. If the tumor presents as a recurrence, it is highly likely that a high amputation should immediately be advised unless a more adequately wide excision could still be performed. In such instances, the size of the resulting defect should not be a barrier for adequate excision as long as proper skin replacement can be achieved. It is not possible to outline typical procedures to be followed for each instance but we are impressed with the

fact that the successful outcome in most instances will be determined by the procedure used at the time of the first surgical intervention

PANCREATIC REFLUX DELIBERATELY PRODUCED

HENRY DOUBILET M.D., F.A.C.S. New York, New York

THE importance of biliary-pancreatic reflux as an etiological factor in the production of acute pancreatitis or acute cholecystitis has been amply demonstrated in recent years (1 3 5 7 8 9)

In the past, pancreatic reflux was demonstrated in about 25 per cent of patients in whom a tube was placed in the biliary tract at operation (2 6) The diagnosis was based on two methods (1) the finding of pancreatic enzymes (notably amylase) in high concentration in the bile recovered from the tube drainage and (2) the visualization of the pancreatic duct when iodized oil was injected into the tube draining the biliary tract

These observations frequently depended on a fortuitous conjunction of events. As a rule pancreatic enzymes could be found in the bili-

ary drainage only occasionally usually after meals (2) but sometimes only in samples obtained late at night (Table I). Similarly the pancreatic duct could be visualized during the performance of a cholangiogram only during such accidental periods when the pancreas was not secreting and when in addition the splenic

Presented in the form of Fundamental Surgical Problems, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

Figs. 1 and 2. Before the administration of morphine (Fig. 1) the injection of iodized oil fills out the common duct, then runs into the duodenum. Only the terminal parts of the hepatic duct are outlined. 15 minutes after subcutaneous administration of morphine, the continued injection of iodized oil results in the visualization of the whole biliary tract. This is due to the increased resistance of the sphincter of Oddi.

Fig. 3 Kymographic tracing of the resistance of the human sphincter of Oddi. Following the administration of morphine, $\frac{1}{6}$ grain, the normal resistance of the sphincter (150 mm of water) rises to 300 millimeters and gradually subsides to 200 millimeters in one hour

ter of Oddi was sufficiently spastic to permit the reflux of iodized oil.

An effort, therefore was made to determine the optimum conditions under which reflux of pancreatic juice could be routinely obtained and the pancreatic duct could be visualized most frequently during cholangiographic studies.

When the resistance of the sphincter of Oddi is normal (about 150 mm of water) iodized oil passes through the common bile duct into the duodenum without filling the fine bile ducts (Fig. 1). Two minutes after the subcutaneous injection of $\frac{1}{6}$ grain of morphine (Fig. 2), the whole biliary tract can be visualized. Kymographic tracings (Fig. 3) reveal these pressure changes clearly (4). One can note however that the resistance of the sphincter which rises

to 300 mm of water comes down to 200 mm at the end of an hour. The intraduodenal injection of hydrochloric acid causes a temporary spasm of the sphincter lasting 10 minutes (Fig. 4). When the sphincter is moderately spastic (Fig. 5) in cases in which the bile and pancreatic ducts join above the sphincter, the iodized oil runs up the main pancreatic duct and out through the accessory pancreatic duct (Santorini) when this duct is present. In the

Fig. 4. The intraduodenal installation of tenth normal hydrochloric acid causes immediate spasm of the sphincter of Oddi. The resistance rises from about 150 to 250 millimeters of water and the effect wears off in about 10 minutes.

Fig. 5 Visualization of the main (Wirsung) and accessory (Santorini) pancreatic ducts. The iodized oil passes down the common bile duct, meets with resistance from the sphincter of Oddi, and passes up the main pancreatic duct of Wirsung and then through the accessory duct of Santorini into the duodenum.

Figs. 6 and 7. Injection of iodized oil shows considerable spasm of the sphincter of Oddi (Fig. 6, left) since the hepatic ducts are outlined to a considerable extent before the oil passes into the duodenum. At the same time, a portion of the pancreatic duct (arrow) is filled. The junction of the common and pancreatic ducts at the ampulla of Vater is clearly visualized. Following the administration of morphine (Fig. 7) the whole biliary tract is outlined. The increased turgidity of the duodenal wall as a result of morphine action causes compression of the intramural portion of both the common and pancreatic ducts. The ampullary junction of these ducts are, however still clearly outlined (arrow).

following case (Fig. 6) one can clearly see the submucosal junction of the two ducts. Two minutes after the injection of morphine (Fig. 7) the whole biliary tract is outlined due to spasm not only of the sphincter but of the duodenal wall through which both ducts pass.

When the bile and pancreatic ducts are connected by a fully unobstructed passageway as in the following unusual case (Figs. 8 and 9) which Dr. Ralph Colp of The Mt. Sinai Hospital kindly allowed me to study, passage of pancreatic juice into the biliary drainage was

Figs. 8 and 9. Injection of iodized oil reveals a hugely dilated choledochus and markedly dilated tortuous pancreatic duct (Fig. 8). The narrow submucosal junction of the two ducts is clearly seen (arrow). Another view (Fig. 9) outlines the whole dilated pancreatic duct as far as the tail.

Fig. 10. Simultaneous collection of T tube bile drainage (5 tubes on left) and duodenal drainage (5 tubes on right) following the injection of secretin in the case illustrated in Figures 8 and 9. The first tube contains drainage of the 10 minute control period, and the following consecutive tubes drainage of 10, 20, 40, and 60 minutes after secretin stimulation. Note the variations in the density especially of the T tube drainage, due to spurts of almost water clear pancreatic juice mixing with the bile.

of quite frequent occurrence. When secretin was administered intravenously to produce pancreatic reflux under controlled basal conditions, it was found (Fig. 10) that about half the pancreatic juice passed into the duodenum while the other half passed up the common bile duct. Gushes of almost water clear bile (containing pancreatic juice) would

Fig. 11. Concentration of amylase in T tube and duodenal drainage following the intravenous injection of secretin in the case illustrated in Figures 8, 9, and 10. The variations in the amylase content of the two drainage fluids appear to be related to the changes in the volume of secretion.

alternate with darker bile coming unmixed from the liver. Similarly the duodenal drainage contained occasional traces of bile but frequently was water clear. The composite result depended on the resistance of the sphincter and the volume of secretion at various intervals.

When this drainage material was examined for amylase (Fig. 11) it was seen that the concentration of amylase was approximately equal in the biliary and the duodenal drainage the

Figs. 12 and 13. Injection of iodized oil in this case in which amylase was recovered in the T tube drainage, revealed a moderately spastic sphincter and a dilated common bile duct (Fig. 12, left). The pancreatic duct (arrow) was visualized following the injection of morphine, only after two previous failures (Fig. 13).

Fig. 14. The optimum conditions for the production of pancreatic reflux. In this case (Table I and Figs. 1 and 3) the injection of secretin was followed by the appearance of amylase in low concentration in the and 30 minute samples only. Morphine stopped all reflux due to spasm of sphincter of Oddi and duodenal wall. Hydrochloric acid intraduodenally produced spasm only of the sphincter and resulted in a maximum reflux of pancreatic juice.

small differences being due to variable admixtures of bile.

However in most cases of pancreatic reflux, amylase was found in the biliary drainage quite infrequently and the pancreatic duct was visualized only after producing spasm of the sphincter of Oddi by means of morphine.

Fig. 15. The relative concentrations of amylase in the T tube drainage and in the duodenal drainage following spasm of the sphincter of Oddi produced by intraduodenal administration of hydrochloric acid (see Fig. 14). This indicates that about one third of the biliary drainage consisted of pancreatic juice.

In the following case (Figs. 12 and 13) the pancreatic duct was visualized by injection of iodized oil only after the third attempt, and amylase was found in the bile after six samples of bile were analyzed.

Accordingly the patient was given intravenously a standard dose (80 clinical units) of

Figs. 6 and 7. The optimum conditions for visualization of the pancreatic duct. Iodized oil was injected into the biliary tract in patient who had been fasted, had all stomach contents aspirated by Levine tube suction for hours previously and had received subcutaneous injection of $\frac{1}{8}$ grain morphine 1 hour previously—note complete filling of pancreatic duct (arrow). Slight rotation of the patient (Fig. 7 right) clearly reveals the anatomical relationship of the two ducts and their junction above the sphincter of Oddi.

secretin and the biliary drainage collected at 10, 20, 40, and 60 minute intervals (Fig. 14). Amylase was recovered only in the 10 and 20 minute samples. When morphine was given just before the injection of secretin no amylase was recovered due to the fact that the spasm produced by the morphine involved not only the sphincter of Oddi but also the duodenal wall, shutting off any reflux. In a third procedure a duodenal tube was passed and following the injection of secretin intravenously 20 cubic centimeters of one-tenth normal hydrochloric acid was introduced intraduodenally every 10 minutes. This produced spasm of the sphincter but not of the duodenal wall and as can be seen a large amount of pancreatic juice (as represented by amylase) was recovered in the biliary drainage. The concentration of amylase recovered in the bile as compared to the concentration in the duodenal contents (Fig. 15) showed that one third of the biliary drainage consisted of pancreatic juice. There can be no question that such procedures which control both the flow of pancreatic juice and the resistance of the sphincter of Oddi will result in the discovery of the maximum incidence of pancreatic reflux.

Similar principles were applied in the visualization of the pancreatic duct by iodized oil. Since two main factors food and hydrochloric acid, stimulate the secretion of pancreatic juice, the patient was fasted and a Levine tube was passed 2 hours prior to x ray examination

for continuous suction of the stomach contents. To control the resistance of the sphincter of Oddi, morphine, $\frac{1}{8}$ grain, was given one hour prior to the cholangiographic study. As the kymographic tracing in Figure 3 demonstrates 1 hour after morphine injection the resistance of the sphincter falls almost invariably to about 200 millimeters of water. By this time the spastic effect of morphine on the duodenum has worn off. When iodized oil was injected into the common bile duct under such conditions the whole pancreatic duct was visualized (Figs. 16 and 17).

CONCLUSION

Therefore it can be seen that control of pancreatic secretion and control of the resistance of the sphincter of Oddi by various means can be utilized to diagnose pancreatic reflux after operation on the biliary tract. Similar methods are being developed now to diagnose this condition on the operating table.

THE EFFECT OF EARLY POSTOPERATIVE RISING ON THE RECURRENCE RATE OF HERNIA

JAMES B BLODGETT M.D., and EDWARD J BEATTIE, M.D., Boston, Massachusetts

THE original article on this subject was written by Ries, a gynecologist in Chicago in 1899. He was impressed by the rapid return of strength in the patients who rose early after operation and he noted the lack of unfavorable complications resulting from early rising. Although the practice of early postoperative rising was taken up by many of the European surgeons it was not widely used in this country until interest in the subject was stimulated by Leithauser of Detroit in 1941 when he published a series of 436 cases. Since the publication of Leithauser's first article there have appeared a number of clinical reports on early postoperative ambulation.

In June of 1942 a critical investigation of early postoperative rising was undertaken at the Peter Bent Brigham Hospital (1). This was to study what effect early ambulation has on postoperative complications, and whether it has any effect on the late operative results. Since postoperative complications are most common among patients having major intra-abdominal surgery this group was used to test the effect of early postoperative rising on postoperative complications. Two hundred and thirty-eight such patients who had risen on the first or second postoperative day were compared with 443 patients who got up after the seventh postoperative day. Our pertinent conclusions of that study were that the incidence of atelectasis was slightly lower in the early rising group (4.6% compared with 6.3%) and that the incidence of deep-leg vein thrombophlebitis however was slightly higher in the early rising group (2.9% compared with 1.8%). With respect to the incidence of postoperative wound disruption there was a slight reduction in the early rising group (1.3% against 2.7%).

From the Peter Bent Brigham Hospital, Surgical Service.
Presented at the Forum on Fundamental Surgical Problems before The Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Today we present the results of a controlled study to determine the influence of early postoperative rising on the recurrence rate of hernia. The control group consists of 301 various herniorrhaphies on 177 patients. These patients got out of bed on the seventh to the fifteenth postoperative day. They were followed from 6 months to 7 years. The test group consists of 174 herniorrhaphies in 139 patients. The majority of the test group rose on or before the first postoperative day; 11 patients rose on the second day. They were all followed from 6 months to 4 years. Interrupted, fine silk technique was used in all cases of both groups.

The technique of getting the patient out of bed is essentially the same as Leithauser's. On the morning following operation the patient is turned on the side operated upon. He flexes his hips and knees so that his lower legs are at the edge of the bed. The nurse holds her elbow in the patient's elbow and the patient pushes his feet off the side of the bed as the nurse assists him up sideways to a sitting position. As the patient sits on the side of the bed slippers with heels, or shoes, are put on before he stands on the foot stool. While standing he is encouraged to breathe deeply and to cough several times. The patient then walks around the bed and sits in his chair for about 20 minutes. As he returns to bed, the walking and coughing are repeated. He is assisted out of bed in this manner twice daily until he can get up himself which in cases of herniorrhaphy is usually on or before the third postoperative day. If the patient wishes to get out of bed on the day of the operation, he is allowed to do so unless there is some specific contraindication. Many of the patients who had had herniorrhaphy performed under local nerve-block anesthesia, got out of bed to eat lunch on the day of operation.

There was no selection among the patients who rose early following herniorrhaphy. The

TABLE I.—THE RECURRENCE RATE OF INDIRECT INGUINAL HERNIAE

Type of operation	Non-early risers		Early risers	
	Number	Recurrence	Number	Recurrence

TABLE II.—THE RECURRENCE RATE OF DIRECT INGUINAL HERNIAE

Type of operation	Non-early risers		Early risers	
	Number	Recurrence	Number	Recurrence
Halssted	7	5	11	4
Bassini	18		20	
Others	McVey 1 Galle 1		McVey 1 Orchidectomy 1	
Totals	25	(6.4%)	31	(4.8%)

group includes older patients patients with poor abdominal wall structures, and patients who had all types of anesthesia and operative repairs.

As a group, the early risers were somewhat older because the younger patients were in the Army during the period when most of the early rising patients were operated upon. As we review the two groups we are again impressed by the rapid postoperative recovery which is found to be present among the group of early rising patients.

In comparing the recurrence rates in the two groups, the results are classified with respect to the method of operative repair¹ and the type of hernia, that is indirect direct femoral incisional and umbilical. Indirect inguinal hernia according to Watson's monograph, carries a recurrence rate of 5 to 10 per cent. Shelley in an exhaustive study of over 1600 indirect inguinal herniae at the New

¹The Halssted repair refers to Halssted's modified repair in which both the conjoint tendon and the external oblique fascia are sutured below the spermatic cord so that the cord is transplanted into the subcutaneous tissue and the external ring approximates the internal ring in position.

TABLE III.—THE RECURRENCES IN FEMORAL, INCISIONAL, AND UMBILICAL HERNIAE

Type of hernia	Non-early risers		Early risers	
	Number	Recurrence	Number	Recurrence
Femoral	8		6	
Incisional				
Umbilical	3		7	

TABLE IV.—TOTAL RECURRENCE RATE OF INGUINAL HERNIAE

Type of hernia	Non-early risers			Early risers		
	Number	Recurrences	Per cent	Number	Recurrences	Per cent
Indirect	131	5	3.8	131	5	4.3
Direct	40	6		36	4	
Totals	170	11	6.5	167	9	5.4

York St Luke's Hospital found a recurrence rate of 7.2 per cent.

Table I gives a tabulation of the recurrences in indirect inguinal herniae. It shows that in the non-early rising group there were 5 recurrences in 131 operations and that in the early rising group there were 5 recurrences in 114 operations. This is a recurrence rate of 3.8 per cent in the non-early risers and 4.3 per cent in the early risers.

For direct hernia, Watson gives the recurrence rate as between 10 and 20 per cent. It may even be higher. As recently as 1942 Page reported a recurrence rate for direct hernia of 35 per cent.

Table II presents a tabulation of the recurrences for direct inguinal herniae which shows that, in the non-early rising group there were 6 recurrences in 49 repairs. In the early rising group there were 4 recurrences among 36 repairs. This is a recurrence rate of 12.2 per cent in the non-early risers and 11.1 per cent in the early risers.

The recurrences in the few femoral incisional and umbilical herniae are listed in Table III. This shows no appreciable increase in recurrences in this small group as a result of early rising.

Table IV gives the total recurrence rate in inguinal hernia. It is seen that the recurrence rate in 170 inguinal herniorrhaphies treated

by postoperative bed rest is 6.1 per cent whereas, the recurrence rate in 150 inguinal herniorrhaphies treated by early rising is 6.0 per cent.

CONCLUSION

We conclude from these data, that early postoperative rising exerts no significant effect on the recurrence rate of hernia.

THE USE OF THE MALE SEX HORMONE IN WOMEN WITH BREAST CANCER

FRANK E. ADAIR, M.D. F.A.C.S. New York, New York

WE have now arrived at the point where it has become profitable to pursue the use of hormone therapy in certain types of human cancer. Huggins made one of the most important contributions that have been made in many years in the field of cancer when he was able to produce 25 per cent cures in prostatic cancer—a disease widely recognized to have an extremely high mortality. His study of the hormone influence in this disease naturally suggested exploration of other fields where cancer is either produced or materially influenced by the sex hormones. Beside the prostate it is patent that other organs such as the breast, uterus, ovaries, adrenal testes and thyroid should each receive serious attention and experimentation.

I recently made a study of 5000 cases of early breast cancer relative to their ages at the time of the development of their cancer.

The peak of the greatest number developing cancer was 45 years. This age probably represents the time when certain chemical changes are present deviating somewhat from the normal ovarian hormone. The ovaries are undergoing at this age certain changes leading up to the menopause which comes on at an average of 46½ years.

On the other hand, the year when next to the greatest number develop breast cancer is age 60 years, and here we probably have a patient who has practically no ovarian hormone output. It is possible that the 13 or 14 years since having a definite ovarian function as evidenced by menstruation may represent a complete lack of ovarian hormone output and may represent a possible cause for the production of breast cancer in the older age group. This theory fits well into the fact that

the women of 60 years and older with breast cancer are improved by the use of the estrogens.

During the past several years my department has been making a clinical experimental study on approximately 200 cases of cancer of the female breast in which testosterone propionate has been employed.

In the beginning the results of this therapy when using small amounts seemed to be of no value (Farrow and Woodward). I next treated 48 patients in my private practice employing a daily dose of 25 milligrams intramuscularly to each patient (175 mgm weekly). It soon became obvious that in certain cases of advanced breast cancer and more particularly in those metastatic to bone, that we were dealing with a very potent agent capable of producing striking clinical improvements as well as changes some of which were demonstrable by x ray films.

Up to this time we had been hampered in our clinical research by the high cost of testosterone propionate, and at this juncture Dr. Henderson of the Schering Corporation generously made it possible for us to commence our new attack employing large doses.

Dr. Julian Herrmann and I then began by giving some patients as much as 100 milligrams daily by intramuscular injections of the agent in oil. We varied the dose using in some instances the testosterone pellets placed subcutaneously in order to obtain a more prolonged absorption of the agent. After much trial and error we arrived at our present dose of 100 milligrams by intramuscular injection three times weekly for a period of 8 to 10 weeks making a total dosage of 2400 to 3000 milligrams. We freely admit that we have not come to a final conclusion as to what should be the exact dose, how much total should be delivered and how long it should be continued. Obviously many of these factors must be determined and will be influenced by whether or not the patient

The studies were made possible by a grant from Mr. Louis Marx to the Breast Service of the Memorial Hospital, New York. Presented in the symposium on Cancer before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

still menstruates, on whether or not her ovaries have been made functionless by x ray or surgical castration as well as many other factors.

At the present time the work is being pursued by my associates and myself not only in the advanced cases but also in the new cases of early operable breast cancer.

It has now gotten almost beyond the point where it is necessary to demonstrate the value of testosterone therapy by giving case reports as we have already placed ample cases in the literature which show the value. We are now at the point where we can draw general conclusions of what may be anticipated by this therapy.

Our experience has shown that in only a small percentage of cases is improvement to be anticipated when the cancer involves the soft tissues such as liver, lungs, brain and local skin recurrence. It is true that in a few instances there have been striking improvements where an advanced ulcerating breast cancer with surrounding skin nodules axillary nodes and neck nodes were involved where masses were metastatic to the lungs and in one instance where the patient was having convulsions from metastatic disease in the brain. However I fear it must at present be taken for granted that most such cases receive no benefit aside from the temporary general improvement which frequently comes as a result of testosterone injections.

On the other hand a most striking improvement is obtained in most of those cases having bone metastasis. There is some specificity or predilection for the agent to do its work of repair in the bone cases—and as yet we do not understand the reason. It is probable in the metabolism of bone repair under the influence of testosterone that the billions of cancer cells are 'snowed under' by the copious deposit of calcium precipitates especially in areas of bone destruction—a locking in process where cell reproduction is difficult. Similar to prostate cases, the cancer cells will still be present after testosterone therapy. We do not yet know whether the improvement of the bone destruction by the invading cancer is confined to cases of breast cancer alone or whether metastasis to bone from some other

type of cancer may also be improved by testosterone such as from thyroid or ovaries. It is important that this study be pursued and that a study in cases of primary bone sarcoma also be carried out.

After approximately 2 weeks of testosterone therapy the relief of pain from bone metastasis is usually very real. Lack of sleep due to pain is replaced by a natural sleep. It is usually possible to cease giving narcotics which may have been given in large amounts. Some of our patients who had such pain that it was not possible to continue their work, were able to return to their jobs in comfort by the end of a month of therapy. The areas of bone destruction as evidenced by absorption of the calcium salts by collapse of vertebrae, and by fracture of ribs are filled in with dense callus similar to that seen following x ray therapy. How long this improvement in the osseous tissue persists is not yet known. However we have 3 cases in which disease was confined to bone having no ascertainable soft tissue involvement living free of evidence of disease or symptoms for a period of 1½ to 2 years after commencing the testosterone therapy.

A brief example of one of these cases was a woman aged 71 years who had been confined to her bed for a period of 10 months, with widespread bony metastases to the spine, pelvis and ribs several of the latter being fractured. After 4 weeks of testosterone therapy she was able to leave her bed. At the end of 3 weeks of therapy she developed as is common the feeling of elation and well being. By the end of 6 weeks she was walking all over the city free from symptoms. The only symptom which bothered her was the annoyance and the irritation of the enlarged clitoris. This patient started on her testosterone therapy in July 1944 and up until December 1, 1946 a period of 2 years 4 months, was living in good health. Three weeks ago she began to have nausea which has persisted, and it may be suspected although not demonstrable that she may have metastases to the liver or to the abdominal lymph nodes. It is not unusual for a patient with metastasis to bone to keep the disease confined there for some time before finally spilling over into soft tissues such as the lungs or abdomen.

Fig. 1. Demonstrating destruction of a large area of frontal bone by metastatic cancer from breast.

Fig. 2. The same patient 10 weeks later following 24 injections, 100 milligrams each, of testosterone propionate, totaling 2400 milligrams. The area of destruction has been filled in by callus and the mass protruding from the forehead has disappeared.

In cases of widespread bony metastasis the use of testosterone propionate seems more efficacious longer lasting and more practical than x ray therapy. When it becomes necessary to treat multiple widespread areas of metastatic bone disease, with the x rays it becomes a matter of great difficulty to deliver so many doses over so many areas not only because of the nausea which frequently accompanies such treatments but there is also the practical problem of bringing a patient who suffers intensely from bone metastasis to the hospital or x ray laboratory furthermore such a large number of x ray treatments may produce an anemia in the face of which x ray therapy itself becomes ineffective.

We have had many instances in which the skin of the patient had been so damaged by x ray therapy that it was not possible or practical to deliver further x ray treatments to the bones. Fortunately it is usually possible in such a case to commence with the testosterone therapy and still obtain some degree of clinical improvement.

In the advanced cases of bone metastasis the blood chemistry is fairly consistent. As a rule such a patient has a blood calcium well above the normal of 10 to 12 milligrams per 100 cubic centimeters. The blood calcium at times goes up as high as 17 milligrams. Under testosterone propionate therapy the rule is that the blood calcium slowly comes back into normal limits theoretically being redeposited in the areas of bone destruction.

The alkaline phosphatase also acts characteristically, it is an enzyme necessary for bone repair. The normal limits are 3 to 5 milligrams. During bone repair under testosterone this figure at times reaches as high as 15 milligrams indicating that bone repair is taking place.

Most of our work to date has been on advanced breast cancer cases. However we have recently started to work on the early operable cases of breast cancer using the radical mastectomy supplemented by large doses of testosterone implanted into the latissimus

dorsal muscle or into the subcutaneous tissues near the wound at the time of the operation. Although we have used this combination in 135 such cases to date we have nothing to report as yet. Two months after the operation we will again implant further doses of testosterone on the theory that possibly recurrence and metastasis may be influenced or lessened by subjecting any remaining cancer tissue to the unhealthy environment of testosterone bearing blood and serum. It is obvious that such a human experiment should be undertaken and evaluated.

It may be of some interest to note that in two pregnant patients with breast cancer receiving testosterone that repeated Aschheim-Zondek tests were negative up to 5 months of pregnancy when the patients could feel life.

It is scarcely necessary to state that the patient receiving testosterone therapy develops unpleasant masculinizing sequelae as evidenced by a deeper husky voice hair on the

face, pimples on the face and body and an enlarged clitoris which in certain cases becomes a source of great annoyance.

On the other hand under testosterone therapy there is usually at least temporarily a gain in weight, a feeling of well being, a loss of bone pain and a repair of the bone destruction caused by the metastatic disease.

As a rule the clinical improvements by the use of testosterone are far more striking than the x ray improvements reveal.

Testosterone may be employed on female patients with breast cancer at any age, while the estrogen therapy must be strictly confined to patients of 60 years and older.

It must be here emphasized that we are not stating that testosterone is a cure for breast cancer however its effects are very profound and gratifying but indicate that much more clinical research must be carried out in the field before we can fully evaluate dosage or final results.

RESECTION OF INTRA-ABDOMINAL CANCER THAT HAS INVADED THE ANTERIOR ABDOMINAL WALL

ALEXANDER BRUNSCHWIG MD F.A.C.S Chicago Illinois

INVASION of the anterior wall by carcinomas primary in the abdominal viscera or invasion of the anterior abdominal wall by metastases from such growths does not constitute a situation in which radical surgical excision is necessarily contraindicated. The primary growth together with its parietal extensions may be excised *en masse* to removal in some instances of all macroscopic evidence of tumor. Such procedures were carried out in a limited group of patients the histories are briefly as follows

CASE 1 J C no 283119, male aged 66 years was subjected to a right hemicolectomy resection of the lower half of the stomach and elliptical portion of the abdominal wall about the umbilicus to remove a large carcinoma of the transverse colon which was spreading to the adjacent structures mentioned. Patient is living and well 4 years and 5 months after operation.

CASE 2 G P no 332661 male aged 63 years, had a resection *en masse* of 16 centimeters of sigmoid

colon an elliptical segment of the parietal peritoneum and deep fascia in the left lower quadrant and segment of the lower jejunum 10 centimeters in length for carcinoma of the sigmoid which was infiltrating the jejunum and anterior abdominal wall. End-to-end enterostomy and double barrel colostomy were performed and the latter was subsequently closed. Patient is living and well 2 years 5 months after operation.

CASE 3 J W no 274690, female aged 34 years. Laparotomy was performed for removal of many peritoneal metastases from a pseudomucinous cyst—adenocarcinoma of the right ovary in 1941. A second laparotomy was done for resection of numerous metastases over the peritoneal surfaces of bowels and in the mesentery of the small intestines. A half fist size mass infiltrating the abdominal wall in the right lower quadrant was excised together with portions of the rectus muscle. Patient is living and well 2 years 2 months after second operation.

CASE 4 J L no 332684 male aged 39 years. Resection of the abdominal wall of the left upper quadrant and subjacent recurrent colon for carcinoma with descending colon spleen containing 4 metastases and tail of pancreas. Double-barrel colostomy was done and was later subsequently closed. Patient is living 1 year 2 months after operation. He has an enlarged nodular liver due to metastases.

CASE 5 P W no 379472 male aged 58 years. A right hemicolectomy was done and 20 centimeters of

From the Department of Surgery, University of Chicago. These studies were aided by the Chas. H. and Mary F. S. Worcester Fund, University of Chicago.

Presented in the symposium on Cancer before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Fig. 1. Diagrammatic representation of operations performed in Cases 1 to 3. Black areas indicate carcinoma.

shaded areas indicate extent of anterior abdominal wall involved by neoplasm and resected.

Fig. 2. Diagrammatic representation of operations performed in Cases 4 to 12. Black areas indicate carcinoma, shaded areas indicate extent of anterior abdominal wall involved by neoplasm and resected.

the lower ileum was resected *en masse* with the abdominal wall of the right lower quadrant for carcinoma primary in the cecum and infiltrating the ab-

dominal wall. Ileo transverse colostomy was made. This patient is living and well 5 months after operation.

Fig 3. Photograph of surgical specimen from Case 5 showing A large segment of lower right quadrant of abdominal wall including skin, subcutaneous fat and musculature infiltrated by C underlying carcinoma arising in cecum, B ascending and transverse colon, I lower ileum.

CASE 6 P. H. L. no 319547 male aged 49 years. An exteriorization excision was done of the sigmoid bearing carcinoma, together with a long loop of the upper ileum invaded by carcinoma, as well as the mesentery of the ileal loop the dome of the urinary bladder and the deeper portion of the anterior abdominal wall in the left lower quadrant. The colostomy was subsequently closed. Patient lived 14 months returned to work for 8 months, but died of recurrences.

CASE 7 E. R. no 160578 female aged 48 years. An elliptical incision 11 by 7 centimeters was made in the left lower abdominal wall to include the mass of recurrent colon carcinoma (previous Mikulicz resection for primary growth) and the involved sub-jacent descending colon. A double barrel colostomy was made. Patient lived 10 months then died of recurrences.

CASE 8 C. P. no 325186, female, aged 55 years. Resection was done of the lower two thirds of the stomach, body of pancreas, spleen, periumbilical region of the abdominal wall, the falciform ligament for carcinoma primary in the body of the pancreas, with local spread and metastases to structures mentioned. Patient lived 4 months. She died of carcinomatosis.

CASE 9 E. L. no 350135 female, aged 68 years. Resection *en masse* was done of previous lower right rectus incision scar with underlying mass infiltrating abdominal wall. Multiple small metastatic masses over the peritoneum also were excised. Patient lived 4 months received palliation.

CASE 10 Gomol no 306534 female, aged 52 years. June, 1943 a supracervical hysterectomy and salpingo-oophorectomy for bilateral cyst-adenocarcinoma of ovaries were done. October 1943 the peri-

umbilical region of abdominal wall *en masse* with underlying and attached tumor 15 centimeters in diameter was excised. The latter was a large metastatic mass, the site of extreme pain. Patient survived 2 months. She died of carcinomatosis.

CASE 11 E. B. no 339809 male aged 28 years. Operation was carried out as follows: total gastrectomy partial hepatectomy partial pancreatectomy transverse colectomy splenectomy resection *en masse* with the above, of the abdominal wall in the left upper quadrant for round cell sarcoma (radio-resistant). Patient survived 3 months died of rapidly developing sarcomatosis.

CASE 12 C. B. no 253457 male aged 48 years. Resection *en masse* was carried out of cecum ascending colon right kidney and ureter 70 centimeters of ileum and abdominal wall in the right lower quadrant for recurrent carcinoma of the cecum.

TABLE I.—SUMMARY OF RESULTS

Case 1	Living and well	4 yrs. 5 mos.
Case 2	Living and well	2 yrs. 5 mos.
Case 3	Living and well	2 yrs. 2 mos.
Case 4	Living but has hepatic metastases	1 yr. 2 mos.
Case 5	Living and well	5 mos.
Case 6	Lived	1 yr. 2 mos.
Case 7	Lived	10 mos.
Case 8	Lived	4 mos.
Case 9	Lived	4 mos.
Case 10	Lived	2 mos.
Case 11	Lived	3 mos.
Case 12	Lived	12 days
Case 13	Lived	5 days†
Operative Mortality—2 Patients		15.4%

*Death from coronary occlusion.
†Peritonitis.

Patient died twelfth day postoperative. Necropsy revealed coronary occlusion.

CASE 13 C F no 297424, male, aged 77 years. Exteriorization resection was done of the descending colon and the musculature of the left flank for carcinoma of the former invading abdominal wall musculature with abscess formation

DISCUSSION

In all instances it was possible to close the wounds tightly following resection of portions of the abdominal wall. There were no wound disruptions. Soft rubber drains were inserted in some cases when suppuration associated with the parietal invasion was obvious. No definite recommendation may be made for these repairs since each procedure represents a special situation. The generally accepted principles of fashioning full thickness (skin, fascia, and sometimes muscle) sliding flaps are followed.

Three patients have survived over 1 year and are living well, and returned to their usual occupations for an average of 36 months since operation. One patient Case 4 received palliation for a year having returned to his usual occupation but at this writing exhibits deterioration due to obvious multiple hepatic metastases.

The results in the series of 13 patients are summarized in Table I. One patient survived 1 year and 2 months dying of metastases, but had returned to work for a period of 8 months. One is living and apparently well 5 months after operation. The patients who survived for shorter periods appeared to have received palliation although this was brief. Operation was performed in these patients because of pain and obstructive symptoms referable to the mass that was excised together with its parietal extensions. Some of the best results were achieved in patients with cancer of the colon which had invaded the abdominal wall. It has long been recognized that such carcinomas may evolve by local spread to adjacent tissues and viscera before distant metastases occur and these results are in accordance with this principle.

SUMMARY

Invasion of the anterior abdominal wall by carcinoma primary in an abdominal viscus does not necessarily indicate that the lesion is inoperable. Palliation and prolonged survival of the patient may follow extensive resections of such neoplasms with their parietal involvements.

OBSERVATIONS ON THE GENETIC NATURE OF GASTRIC CANCER IN MICE

LEONELL C. STRONG Ph.D., Sc.D. New Haven, Connecticut

THE practice and science of medicine being based exclusively or even predominantly upon the science of bacteriology the conclusion is inevitable to some investigators that a cell or an individual is incapable of doing anything without being impinged upon by some external force. The science of genetics, stemming from the study of embryology teaches differently. Genetics teaches that a zygote that is the fertilized egg when placed in a suitable environment of temperature and humidity, given a few specific chemical entities such as the essential amino acids and the vitamins and a source of energy is capable by development from spatially related internal nuclear entities or genes of giving rise to an adult plant or animal. This determination is so precise that many racial, familial, and individual characteristics are handed down from one generation to the next. This process of heredity has undoubtedly been going on from immemorial time and it probably will go on in the future subject to change only by the sporadic appearance of mutations from time to time. It is the present intention to see whether this concept of biologic determination can also be applied to cancer particularly to cancer of gastric origin.

In the first place all cells of the body are derived by cell division from the zygote. Since cells and tissues reproduce physiological and morphological characteristics of their species in each and every generation they must, of necessity retain many potentialities from their zygotic origin. Superimposed upon this background of intrinsic determinations are many variations necessitated by environmental changes which are not of necessity hereditary. Now cancer is derived by cell division from some somatic tissue and therefore must

retain some potentialities derived from the zygote.

The production of gastric carcinoma in mice was the result of the practical application of genetic principles by which the attempt was made to duplicate or to simulate in mice the variable biological state of the human population. For this purpose the genetic processes of hybridization and selection were used. In addition however each mouse received the subcutaneous injection of 1 milligram of methylcholanthrene dissolved in 0.1 cubic centimeter of sesame oil at 60 days of age. This procedure of injection has been followed for both parents for many generations. Beginning with the early hybrid generations the tendency to give rise to local tumors at the site of the injection of the carcinogen has been suppressed by keeping the descendants of the most resistant to cancer pair of mice in each generation. Due almost exclusively to this regimen of selection toward resistance to induced cancer there has been produced an increased latent period for the appearance of not only locally expected tumors but also of other types of tumors which appeared due no doubt to the fact that the selected hybrid mice with increased biologic variability lived longer than they normally would following the injection of methylcholanthrene. Four stages or classes of mice based upon the classification of induced tumors have appeared in this selection experiment as follows: (1) the appearance of tumors such as epidermoid carcinoma and fibrosarcoma at the site of injection of the carcinogen; (2) the surface spread of tumors over the entire body such as carcinoma of the mouth, the rectum, etc.; (3) the appearance of tumors in the thoracic cavity such as adenocarcinoma of the lung, bronchiogenic carcinoma and mesothelioma; and (4) the occurrence of tumors appearing in the abdomen such as primary carcinoma of the liver, liposarcoma of the uterine mesentery, leiomyosarcoma of the uterus and gastric

This experiment has been made possible by grants from The Jane Coffin Childs Memorial Fund for Medical Research and The Anna Fuller Fund. Presented in the symposium on Cancer before the Clinical Congress of The American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

carcinoma. Beyond these four stages where specific types of tumors occurred there was obtained a period, of short duration in which no tumors appeared in spite of the fact that an overwhelming dose of a very powerful carcinogen had been injected. Even with continued selection toward greater resistance to all types of induced tumors, there occurred a reversal of susceptibility to induced cancer in which tumors appeared earlier and earlier in the succeeding selected generations. For the present purpose however we shall confine ourselves to the gastric carcinomas which began to appear in stage 4 enumerated above. These gastric lesions showed histological variability some growing as polyps, while others grew invasively through the underlying muscular layers of the stomach. Metastases into the surrounding viscera have also been obtained from these adenocarcinomas of gastric origin. When a suitable genetic experiment had been performed, it was demonstrated that the susceptibility to give rise to this gastric lesion showed linkage relationship with the gene that underlies brown hair pigmentation. Thus it is clear that a mutation has occurred on the brown chromosome sometime during the extent of the injection of methylcholanthrene into mice and that this mutation is responsible in part, for the development of gastric carcinoma following the subcutaneous injection of methylcholanthrene. Another point of genetic interest is the fact that the untreated descendants of these mice which had developed gastric carcinoma following the subcutaneous injection of methylcholanthrene continued to develop gastric carcinoma spontaneously and they have continued to do so through eight untreated generations. At periodic times during the experiment of injecting both parents at sixty days of age with methylcholanthrene a group of 120 mice have been separated off and kept under standard laboratory conditions without being subjected to any experimental procedure. In the succeeding groups of 120 mice referred to above the incidence of spontaneous gastric lesions and carcinomas increased in frequency and, at the same time appeared earlier and earlier in life. Now there is available a strain of mice in which all individuals develop gastric lesions or carcinomas

or some closely related biological entity spontaneously the males, however showing a greater susceptibility to gastric lesions than do females.

In addition to these gastric lesions of unusual origin there has also been obtained several adenocarcinomas and squamous carcinomas of the forestomach which may serve as a source of material for other types of neoplasia induced by a subcutaneous injection of methylcholanthrene. In the gastric lesion, some of which are undoubtedly adenocarcinomas, it is clear that we have produced a hereditary disease or an inherited susceptibility to a disease by chemical means.

In his very excellent book on the "Foundations of Zoology" Professor W. K. Brooks had this to say "If like Paley I kick a stone I may change its position, raise its temperature, and bring about other changes that might all be computed from a few simple data. What happens if instead of a stone, I kick a dog? What a difference between a kick against a dog and one against a stone! In one case the simple conditions may be stated in a few words, and the result may be computed while in the other, a book would not suffice for the statement of all the facts, and the best science of our day is powerless to compute the result." This illustration is used to discuss the theme of the entire book of the relation of stimulus to intrinsic constitution in biologic response or behavior. Perhaps it is not too far fetched to apply this concept to cellular physiology especially to cancer. One may insult a cell by a multiplicity of agents such as bacteria, viruses, hormones and vitamins, but, in the last analysis, how the cell responds or even acts or fails to respond is due to no small degree to its intrinsic genetic constitution determined, in part by its origin from the zygote. It is this genetic concept of the nature of intrinsic biologic variability together with chemical induction, that is making possible the development of many benign and malignant tumors in mice. A concept to be of value should not only explain the contributions of the past, but should pave the way for new contributions. It is not out of place to point out to an assembly of surgeons that the cancer problem has not been solved and therefore we should not expect to find the

solution in the literature. Rather should it be desirable to advance in the study of cancer by producing more and more malignant conditions in experimental animals that duplicate or even approach the types of tumors that are killing more and more men and women at an ever increasing rate. For this purpose the genetic concept of cancer has justified itself and

should be of more than an academic interest.

In conclusion it may be pointed out that if genetic principles of hybridization, selection and inbreeding are capable of giving rise to a great multiplicity of tumor types then the reverse of these same genetic principles should lead to the building up of a biologic state that will refuse to give rise to cancer in any form.

CORRELATION OF THE USE OF ANTIBIOTIC AND CHEMOTHERAPEUTIC AGENTS WITH GENERAL PRINCIPLES OF SURGERY

CHAMP LYONS M.D. New Orleans, Louisiana

THE introduction of potent chemotherapeutic and antibiotic agents challenged many traditional concepts in the surgical management of infections. A new group of nonsurgical specialists has arisen from the ranks of internists to concern themselves with the drug treatment of infections previously considered as surgical diseases. Paradoxically this trend has not been correlated with a diminishing surgical responsibility for the treatment of impending or established infections. In fact the net impact of this challenge has been the visualization of new fields for surgical exploitation. Entirely apart from the generally acknowledged necessity for the surgical drainage of pus there are four major problems of clinical concern: (1) treatment of impending wound infection; (2) treatment of mixed infections due to both gram-positive and gram-negative bacteria; (3) treatment of the intravascular complications of bacteremic infections; and (4) rôle of antibacterial agents in surgical management.

It is interesting that the dramatic accomplishments of the era of antibacterial therapy have so little altered the integrity of estab-

lished and fundamental principles of surgery. Controversy has attended problems requiring surgical judgment, but control of the capricious quality of bacterial invasiveness has made more clearly evident the violation of fundamental biologic laws. The broad diagnosis of infection can no longer absolve errors in diagnosis, judgment or technique. It is the purpose of this discussion to summarize the basic surgical principles validating this viewpoint.

TREATMENT OF IMPENDING WOUND INFECTION

Experience in wound management among military surgeons in World War II crystallized much opinion about matters apparently still controversial among civilian and experimental surgeons. The major point at issue is the logic of local chemotherapy. Military experience justifies the abandonment of local chemotherapy in all wounds except occasional complicated wounds of serous cavities or major joints. Included in this philosophy of wound management is abandonment of the concept of prophylactic use of chemotherapeutic and antibiotic agents. Prevention of infection is an exercise in surgical technique. Antibacterial agents are reserved for the treatment of impending infection upon indications derived from clinical appraisal of the wound. Thus, chemotherapy is solely an adjuvant to surgical competency in wound management.

From the Department of Surgery, Tulane University School of Medicine and the Department of Surgery, Ochsner Clinic.

Presented in the symposium on Antibiotic and Chemotherapeutic Agents in Surgery before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Wound infection may be subdivided into two major components: invasive infection and wound suppuration. The invasive bacteria, capable of destroying living tissue, are the hemolytic streptococcus, toxigenic clostridium and staphylococcus. All are susceptible to penicillin therapy with occasional strain exceptions. Wound pathogens, responsible for wound suppuration, are a more heterogeneous group and relatively resistant to currently available chemotherapy. In addition the wound pathogens demand a nutritional pabulum other than living tissue within the wound. Devitalized tissue, blood clot and serous exudate in an open wound are removed naturally by septic decomposition; hence, the existence of such a pabulum is of greater clinical importance than the identity of the bacteria concerned with its liquefaction. The initial surgical care of the wound and the use of splints and pressure dressings are far more practical than attempts to sterilize residual dead tissue or exudate within the wound. In other words, the surgically clean soft part wound requires no local chemotherapy and no amount of chemotherapy can sterilize an imperfectly debrided wound.

The living tissues of the wound are best protected from the ever present hazard of invasive infection by perfusion with a blood borne antibacterial drug. Systemic therapy achieves this objective. It has been learned that the surgically clean soft part wound risks invasive infection only by the hemolytic streptococcus and that sulfonamide therapy adequately anticipates this danger. However residual blood clot has been found as potentially acceptable as dead muscle as a nidus for clostridium infection. The greater antibacterial potency of penicillin for clostridium and staphylococcus makes it the drug of choice for wounds with residual hematoma or devitalized tissue. Such wounds are the complicated soft part wounds and compound fractures.

Again clinical expediency has dictated the abandonment of routine bacteriologic culture of wounds as an index of infection. The gross pathologic appearance of the wound 3 to 10 days after initial surgical treatment is the best evidence of the adequacy of the initial excision and the presence or absence of infection. It is

this general principle which underlies the two-stage technique of wound management. A further development of importance is the segregation of reparative and reconstructive phases of wound management. Postponement of reconstructive procedures to an elective schedule during convalescence and after wound healing has yielded greater success in ultimate rehabilitation.

TREATMENT OF MIXED INFECTIONS DUE TO BOTH GRAM POSITIVE AND GRAM NEGATIVE BACTERIA

Evidence for the minor rôle as wound pathogens of the gram-negative bacilli of the coliform group is gradually appearing. Even in peritonitis and bronchopulmonary suppuration penicillin appears to be optimally effective when used in dosage adequate to control the gram-positive components of the infection. A similar conclusion has been reached in the study of wound infections.

This reasoning does not extend, however, to infections of the urine, bile or cerebrospinal fluid. These body secretions contain an abundance of essential metabolites for bacterial growth and are deficient in sulfonamide inhibitors. Under the circumstances of mixed infection of the urinary, biliary or cerebrospinal system, the combination of penicillin and either sulfonamide or streptomycin may be desirable. To be effective chemotherapy must be combined with restoration of normal flow for these systems.

TREATMENT OF THE INTRAVASCULAR COMPLICATIONS OF BACTEREMIC INFECTIONS

The reduced mortality rate in bacteremic infections offers the most convincing proof of the potency of presently available antibacterial agents. A consequence of this improved survival rate is an increasing incidence of residual complications of previously infrequent occurrence. Many unusual abscesses, such as the gas abscess of the retroperitoneal space as a complication of gas gangrene of the thigh, have been noted. Such abscesses rarely present problems in diagnosis or management. However there are certain residual lesions of the vascular bed which are important for recognition and merit discussion as to principles

of treatment. These may be considered in two major categories: first the intravascular foci of suppuration and, second, the metastases therefrom.

The intravascular foci of suppuration may be surgically accessible or surgically inaccessible. That surgical excision of all septic thrombi is not mandatory may be deduced from the experience with endocarditis and cavernous sinus thrombophlebitis. That conservative management is not uniformly successful is apparent from the experience with pyelophlebitis. In the treatment of these lesions it is important to record the gradual abandonment of concomitant anticoagulant therapy in consequence of hemorrhagic complications.

The septic thrombi amenable to surgical attack are those associated with endophlebitis of the peripheral veins. Most frequently involved are the veins of the pelvic, jugular and saphenofemoral systems. The essential pathologic changes of septic endophlebitis render unlikely the detachment of a sufficiently large embolus to produce immediately fatal pulmonary infarction. Most commonly progressive septic infarction of the lung and subsequent focal pneumonitis result. More rarely there is an extending thrombosis of a major venous trunk. Such a process in the inferior vena cava with ultimate occlusion of the renal veins is associated with renal shut down and death from uremia. The life endangering qualities of these complications justify surgical intervention for any accessible focus of septic endophlebitis.

The possibility of septic endophlebitis is suggested by recurrent chills, spiking fever and persistent leucocytosis. The early diagnosis of progressive thrombosis or septic pulmonary infarction is not always easy. The septic emboli in the lung are usually microabscesses and cast no shadow in the roentgenogram. The characteristic radiologic evidence of multiple rounded areas of lightly increased density is dependent upon the development of pneumonitis around the areas of infection. It is characteristic of these lesions that as the process of suppuration in the site of the septic emboli progresses, tension pneumothorax, pyopneumothorax, empyema and abscess formation are features of the suppura-

tive phase demanding appropriate consideration and treatment. Although the ultimate healing of multiple pyogenic abscesses of the lung is remarkably complete in the survivors, early venous interruption is the preferred method of treatment. Local tenderness over a likely venous pathway may be the only clue to the particular site of venous involvement. More rarely, the differential diagnosis of septic endophlebitis and endocarditis of the right side of the heart may require consideration.

Ascending septic thrombophlebitis of the inferior vena cava is usually a complication of an obvious focus of inflammation or abscess of the pelvis or lower extremity. The clue to caval extension of the septic thrombus is massive edema of the extremity at the time of iliac involvement.

As a general principle it may be stated that excision of the affected segment is preferable to proximal ligation. Suppuration of the distal stump such as occurs spontaneously in the veins of the face may demand venotomy for drainage of pus. On the other hand technical considerations dictate simple ligation of the inferior vena cava. This is readily accomplished through a right-sided retroperitoneal approach unless the necessity for concomitant interruption of the ovarian veins dictates a transperitoneal approach.

Another complication and a little emphasized feature of the successful treatment of endocarditis of the left side of the heart is the occurrence of mycotic aneurysms. Early diagnosis of these lesions is mandatory if surgical treatment is to be successful. No method of aneurysmorrhaphy is applicable to the septic and necrotic wall of these aneurysms. The only practical method of treatment is proximal ligation. Fortunately many of these patients are sufficiently youthful so that adequate collateral circulation will develop after such an arterial interruption.

ROLE OF A THROMBOTIC AGENT IN THE OVERALL PROGRAM OF CLINICAL MANAGEMENT

The chronically ill patient depleted by persistent infection can rarely be cured by chemotherapy alone. This has been especially emphasized by the experience with actinomycetosis in which the recurrent nature of the disease

PHYSIOLOGIC ASPECTS OF SURGICAL INFECTIONS

JOHN S. LOCKWOOD M.D. Med. Sc. D. New York, New York

THE direct attack on the bacteria involved in surgical infections has been increasingly effective during the past 10 years. Scarcely a year has elapsed without bringing forth a new chemotherapeutic weapon better for some bacteriological purpose than those hitherto available. However there is ample evidence to indicate that the proper management of infections calls for much more than the ritualistic administration of the right drug for the right organism. It seems appropriate in this symposium to recall attention to three primary reservations which should temper the purely bacteriological approach in the management of surgical infections (1) Chemotherapeutic agents and antiseptics are only useful when they aid rather than interfere with the natural defense and recovery mechanisms of the body in infection the process which Fleming calls 'physiological antiseptics' (2) Effective management of many wounds infested with bacteria requires correction of an unhealthy physiological condition rather than a direct attack on the bacteria (3) In severe infections of almost all types there usually occur profound toxic functional derangements of organs and systems not immediately involved in the infectious process and the chemotherapeutic agents administered will not of themselves serve to remedy the consequences of such disorders.

It is the purpose of this paper briefly to discuss these three aspects of surgical infections and to indicate that the use of our new found weapons against bacteria must be handled with an understanding of their limitations so that we may at all times recognize the ultimate importance of guarding and implementing the physiological mechanisms of recovery from infection whether the infection be in a wound or a systemic invasive infection. The

principles to be discussed are by no means new in fact some of them were clearly recognized long before the discovery of the sulfonamides and penicillin. First will be considered some of the physiological aspects of treatment of localized tissue infections, or infected wounds, and next will be taken up the subject of toxemia in infection.

Sir Alexander Fleming writing of the investigations on wounds during World War I, performed by himself and other members of a research team led by Sir Almroth Wright, made the following significant statement "In view of the observations I have made, and which are quoted above I venture to suggest that the antiseptics at present in use will only exercise a beneficial effect in a septic wound if they possess the property of stimulating or conserving the natural defensive mechanism of the body against infection. If such a thesis be true, then it brings the antiseptic and the physiological treatments on to the same basis and it also makes it necessary in the estimation of the value of an antiseptic, to study its effect on the tissues more than its effect on the bacteria.

The evidence in support of these assertions was largely drawn from a series of laboratory experiments on wounds *in vivo* or on wound exudate *in vitro* with conditions which simulated as closely as possible the actual conditions existing in the wound. It was demonstrated that the ability of bacteria to multiply in wounds is conditioned to a very large extent by (a) the reaction of the exudate loss of alkaline reserve being conducive to bacterial proliferation and (b) the antitryptic capacity of the serum or lymph the presence of a low degree of antitryptic power tending also to encourage bacterial growth. Many bacteria lack the equipment of enzymes necessary to break down complex proteins into assimilable amino acids and peptides and the presence of active proteolytic enzymes in the bacterial environment presumably permits organisms of low

chronic empyema of pleural decortication under the protection of penicillin demonstrates how a chemotherapeutic agent may aid the surgeon in attaining a physiological objective. In many long-standing leg ulcers the factor of superficial infection contributes to their chronicity, but success in eliminating the hemolytic streptococci staphylococci or colon bacilli will not alone allow the ulcer to heal if the poor circulation in the fibrous ulcer bed cannot sustain the growth and continued vitality of an epithelial covering. Permanent healing may await restoration of normal blood flow in the affected extremity, removal of scar tissue, and application of grafts of healthy skin. There is now ample evidence that chemotherapy and other forms of local treatment of large decubitus ulcers are gestures of futility unless the nutritional debility of the afflicted patient is first corrected and when that has been done and all dead tissue removed plastic closure of the ulcers can be performed successfully in the face of a very considerable amount of bacterial contamination.

The large scale clinical investigation of the use of topical sulfonamide applications in prevention of infection in civilian accidental wounds, which was carried on under the OSRD during the war served to bring out very clearly the primary importance of the physiological condition of the wound and emphasized the limitations of chemotherapy in meeting this problem. Conclusions from this study (3) were recently summarized

"1 Factors tending to delay or interfere with wound repair such as extensive tissue trauma, incomplete débridement, or improper or ill advised closure with tension, residual dead-space or implantation of foreign materials, will always predispose to the development of infection in accidental wounds.

"2 The use of chemotherapeutic agents in any combination and by any route does not prevent local infection of the wound when these predisposing factors exist.

3 Chemotherapeutic agents are probably of great value in preventing invasive sepsis and death from infection following accidental wounds."

Therefore the surgeon who attempts to lean heavily on the crutch of prophylactic

topical sulfonamides in the performance of reparative surgery will sometimes be disappointed, and many of his good results will have been obtained in spite of rather than because of the application of the drug. However, there appears to be a valuable place for the local use of penicillin, and perhaps streptomycin as well in the treatment of many established infections of wounds, in localized abscesses, acute empyema, suppurative arthritis and perostitis, meningitis, mastoiditis, and bronchiectasis. This practice is in keeping with physiological management if the antibiotic is also given intramuscularly in full doses to control such invasive aspects of the infection as may be present, and if the topically applied drug is dissolved in a suitable vehicle. The vehicle which has given the best results in cases under my own observation has been normal saline, containing 1000 to 5000 units of penicillin per cubic centimeter administered either by intermittent aspiration and injection as in acute arthritis and empyema or in the case of infected wounds, by intermittent irrigation through a very small indwelling tube which is held in place by the dressing or by loose gauze packing. In order to achieve the maximum effect, the drug must be applied so as to maintain a high concentration continuously in all parts of the wound.

Therefore, to summarize this initial phase of our discussion the primary concern of the surgeon in the care of the localized infectious lesion should be to conserve and augment the natural mechanisms of the body for combating infection. Surgical procedures can be of great value in removing tissues which have lost their capacity to react to infection in improving blood supply, and in providing physiological conditions favorable to healing. Penicillin, streptomycin and the sulfonamides will display their greatest value if used with proper discrimination in conjunction with surgery directed toward these ends.

The need for constant attention to the physiological mechanisms of infection is even greater in the management of severe invasive infections, such as peritonitis, septicemia, and gas gangrene where their derangement seriously threatens the life of the patient. As one studies these infections at the bedside and in

the experimental laboratory one is increasingly impressed with the similarity between the physiological condition of patients with severe infection and that of patients in shock due to blood loss, to crush syndrome to intestinal obstruction or to severe burns. Much of what has been learned about the prevention and treatment of shock during the last war may properly be applied to the treatment of patients with severe infections.

As used here the term shock connotes an acute maladjustment in the distribution of sufficient available oxygen in the blood to meet the needs of critical organs of the body particularly the liver adrenals, kidneys, and heart muscle. Shock as so defined may be initiated not only by reduction of blood volume below that required for maintenance of circulatory dynamics but also by loss of peripheral vascular tonus by failure of proper oxygenation of the blood and by a pathological alteration in the composition or physical condition of the blood.

Pentonitis perhaps illustrates the various aspects of shock in infection better than any other surgical infection because it brings into simultaneous interplay a number of factors which contribute to development of shock as it has been here defined. During the past 2 years I have had the opportunity of studying this subject extensively in dogs in the experimental laboratory in collaboration with Doctors John H. Kay and Donald G. C. Clark (3, 9, 10). During the critical period of the disease salt and water are lost externally in vomitus, or in decompression of the paralyzed bowel and internally into the edematous peritoneum and intestinal wall. Plasma protein is taken out of circulation in the process of formation of peritoneal exudate. Many red cells are destroyed by hemolysis and others are lost from effective use as oxygen conductors by stagnation in the engorged vessels of the peritoneum and by the formation of sticky conglutinated masses of what Knusely has aptly called sludge. All of these factors unless corrected, contribute to the development of a progressively falling blood volume. However replacement of the lost volume of blood does not necessarily relieve the shock state in peritonitis, a fact which was demon-

strated during the war by Emerson and Ebert. One reasonable explanation of this is that the lysis of Gram negative bacteria present in the exudates of peritonitis permits the liberation of endotoxins into the portal and systemic circulations, which specifically impair the functions of capillaries and of cell membranes not only in the liver to which these toxins are presumably carried in their most concentrated form but in other essential organs as well (14, 15). Therefore, the shock state in peritonitis is probably compounded of reduced blood volume, plus the direct toxic action of products of bacterial and tissue origin. An interesting practical sidelight on the activity of endotoxins of Gram negative bacilli is the evidence now available from several sources (16) that the sulfonamides exercise a nonspecific protective action in animals against the lethal effects of such toxins. The beneficial use of sulfonamide prophylaxis and treatment of peritonitis may be attributable as much to this antitoxic action as to the repression of bacterial growth in the peritoneal cavity. We should therefore not be hasty to abandon entirely the use of sulfonamides in peritonitis in favor of the newer antibiotic agents, such as penicillin and streptomycin until opportunity has been afforded to study more fully the comparative usefulness of these agents in combatting the factor of toxemia.

Still another physiological system which appears to be thrown out of balance in peritonitis is the equilibrium between the plasma proteolytic enzyme and its respective inhibitor. This is essentially the same system which Fleming was concerned with in his study of wound exudates, to which reference was made in the first portion of this paper. The proteolytic enzyme which is normally available for activation in plasma and which is most readily demonstrated through its lytic action on fibrinogen and fibrin, presumably exists for the most part in the form of an inactive precursor. However just as is the case with pancreatic trypsin which it resembles, the plasma protease may become converted to its active form through contact with activators of bacterial and tissue origin. The so called fibrinolysin of the hemolytic streptococcus is, in fact, merely an activator of the

plasma proteolytic enzyme system and in conformity with conventional terminology, has been renamed 'streptokinase' (12). The action of the plasma protease is normally counterbalanced by a circulating inhibitor factor corresponding to and closely resembling the pancreatic trypsin inhibitor. However it was found (10) that in the crisis of peritonitis in the dog this equilibrium is thrown out of balance and the 'escape' of the lytic principle is evidenced by an increase in the lytic activity of plasma against both fibrinogen and fibrin. Lysis of circulating fibrinogen and perhaps of prothrombin as well appears to explain why the blood of animals and patients in shock from peritonitis and from other causes sometimes fails to clot. The work of Grob suggested a method of determining the significance of increased plasma proteolytic activity in the pathogenesis of peritonitis. He had shown that increasing the titer of protease inhibitor by repeated intramuscular injections or oral feeding of trypsin is accompanied by a marked increase in the ability of animals to withstand the local digestion of tissues caused by subcutaneous injection of proteolytic enzymes of animal and bacterial origin. My colleagues and I therefore undertook to evaluate the protective influence of repeated trypsin injections against the lethal sequences of appendiceal peritonitis, and obtained an interesting result. Peritonitis was produced in 18 pairs of dogs by appendiceal ligation; one of each pair had received daily intramuscular injections of crystalline trypsin for 12 days and the other was a control. The management of the animals was in all respects identical and the healthier looking dog of each pair was always selected to be the control. The end-result was the survival of 15 trypsin prepared animals and of only 6 controls. The animals which had received trypsin preparation failed to display many of the morbid clinical and laboratory signs which were conspicuous in the controls. It may be added that efforts to influence the morbidity and mortality of the experimental disease in dogs were far less successful when chemotherapeutic agents were employed. The mortality rate in 15 dogs treated with large doses of penicillin was 33 1/3 per cent (10). These experimental studies are

mentioned here in order to indicate that there are important aspects in the morbid process of an established infection which are not likely to be countered solely by the administration of bacteriostatic chemotherapeutic drugs. We must continue to recognize that the infected patient is a more complicated system than a laboratory culture and that recovery from infections requires the stabilization or readjustment of many physiological disturbances which the infection has created.

Therefore in treating the toxemia of severe infection, all possible use should be made of penicillin, sulfonamides, and streptomycin but the fundamental physiological disorders that derive from bacterial infection must also be kept in mind, so that adequate supportive treatment, as well as chemotherapy may be given. The following aspects of supportive treatment deserve particular emphasis.

1. Patients with serious invasive infections including peritonitis, bacteremias of all types, gas gangrene, and meningitis should be handled with the same concern for maintenance of blood volume as is employed in modern treatment of severe burns, and of hemorrhagic or postoperative shock. This will require generous use of whole blood, of plasma, and of saline and glucose solutions guided by frequent estimations of hematocrit, serum proteins and electrolytes and urinary output.

2. These patients should not be permitted to suffer from even temporary protein starvation. The patient with an acute infection is undergoing very active protein catabolism; the quantity of nitrogen excreted in the urine reflects a utilization of protein which is equivalent to three or four times the normal daily requirement. Still more is being continuously lost in the formation of inflammatory exudates. For example a patient with empyema may be losing the equivalent of a pint of plasma each day in the form of purulent thoracentesis fluid. Unless an equivalent amount of protein is supplied in the diet or by parenteral injections a rapid depletion of liver and muscle protein is bound to occur, thereby undermining the resistance of the patient and aggravating the problem of his convalescence. All patients with infections should be maintained on a high protein, high caloric intake and a

record should be kept of the amounts of food actually ingested. If oral feeding is contraindicated protein should be given parenterally by a suitable hydrolysate, with glucose. The average adult patient should receive at least 125 grams of protein and 2500 calories, daily.

3 The utilization and excretion of several of the vitamins is much increased during acute and chronic infections. After studying the requirements of patients in shock from various causes Levenson and his associates have recommended the following daily doses of vitamins during the period of acute stress

Ascorbic acid	50 gram
Thiamin	50 mgm.
Riboflavin	50 mgm.
Nicotinic acid	500 mgm.

After the period of critical illness has passed these doses may be reduced to approximately one fifth of the above figures.

In view of the possibility that some of the physiological derangements in severe infections are related to inadequate storage of these vitamins, this aspect of balanced supportive treatment should not be neglected.

4. Since the absorption of toxic breakdown products of bacteria and tissue is still the basis of toxemia in infection much caution should be exercised before abandoning to chemotherapy exclusively the treatment of conditions in which surgical intervention has been our principal life-saving weapon in the past. The evidence may now justify the nonoperative treatment (1) of acute hematogenous osteomyelitis and other invasive infections where the susceptibility of the causative bacteria to penicillin may in most cases be assumed, but it is doubtful that chemotherapy will ever be more than a valued adjunct to surgery in the treatment of conditions such as appendicitis and its complications, and chronic pulmonary suppuration and gas gangrene. Penicillin in large doses may be of definite value in established peritonitis following neglected appendicitis, as the recent report of Crile has shown but it will not compete with surgery as the principal treatment of choice in acute appendicitis.

SUMMARY AND CONCLUSIONS

1 Chemotherapeutic agents should be selected, and used, with a view toward aiding in the natural resistance of the body to infection.

2 Although it is important, wherever possible, to employ treatment directed specifically against the bacteria involved in an infection, the treatment of associated disorders should not be neglected. In certain conditions the persistence of the infection is entirely dependent on an underlying physiological lesion, and in these cases, chemotherapy is of only secondary importance.

3 Rational treatment of severe infection characterized by toxemia demands supportive measures as well as administration of chemotherapeutic agents. Particular attention must be given to maintenance of blood volume, provision of an adequate intake of protein, calories and vitamins, and surgical removal of the cause of the toxemia.

4. Study of the pathologic physiology of the toxemia of infections should be encouraged, in the hope that mortality from these conditions may be still further reduced.

SYMPATHETIC INTERRUPTION IN CASES OF TRAUMA AND IN POSTTRAUMATIC STATES

HARRIS B SHUMACKER Jr., M.D., New Haven Connecticut

THERE can be no doubt that an erroneous impression has persisted from the past concerning the favorable influence of war upon medical progress. Actually the period of war must be recognized as having resulted in retardation of progress as compared with what might have come from a period of peace whether measured by the health and longevity of the world population the adequacy of undergraduate and graduate training of physicians or the advancement of fundamental and applied knowledge. It behooves us then to salvage from the war effort all accomplishments which may be useful in the conduct of any future military engagement and more particularly those contributions which may aid in peacetime practice.

In the recent conflict not only was military medicine on a higher plane than in any preceding war but circumstances permitted a better evaluation of the preventive diagnostic and therapeutic means which were utilized. Of especial importance in this regard was the creation by the Surgeon General of special centers for the care of certain types of injuries and disease, a plan which made possible careful study of these disorders and of their treatment under favorable circumstances by a group of medical officers competent for this task by special interest and professional preparation. Their study was however necessarily limited more or less to the later manifestations of these conditions, although prompt evacuation sometimes placed in their hands patients ill or disabled for only a few weeks. In addition, in spite of the difficulties resulting from the necessity for prompt evacuation of patients certain deficiencies in facilities and other cir-

cumstances arising from military demands a considerable number of very informative reports have come from the Forward Areas. Such contributions naturally are attributable primarily to the proficiency and scientific interest of those who conducted them. Great credit must be given however, to the Surgeon General's Office and to the consultant system utilized in the various theaters of command and to their earnest, if not always successful efforts to assign duties to medical officers according to their training and ability, to support them whenever possible with adequate equipment and to stimulate the careful recording of case records.

The segregation of patients with vascular disorders and abnormalities involving sympathetic function in the Vascular and Neurosurgical Centers permitted a study of many of the problems for which sympathetic interruption has been recommended as beneficial in numbers rarely if ever before approached. This information has been supplemented by observations of these and allied conditions in Forward Areas. It is the purpose of this communication to inquire into the rôle of temporary and permanent interruption of the sympathetic nerves in the care of patients who have sustained trauma. No detailed analysis will be attempted but rather a general presentation of the problem as it developed in my own experience and as it has been presented by other medical officers in the current American literature. For the sake of brevity I shall omit reference to the valuable work of numerous investigators whose contributions before the war established the principles and fundamental background for the application of sympathetic interruption in the surgery of warfare. One cannot emphasize too strongly the value of these investigations. Certain personal observations from the recent war have already been recorded in more detail elsewhere by my associates and me (26-29) and other reports

From the Vascular Center, the Mayo General Hospital, Galesburg, Illinois, and the Department of Surgery of the Yale University School of Medicine, New Haven, Connecticut.

Presented in the symposium on Fractures and other Traumas before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

covering sympathetic interruption in such conditions as the post traumatic vasomotor disorders, cases of injury to major arteries, causalgia, and frostbite will be reported subsequently. The problems under consideration will be discussed primarily from the standpoint of the efficacy and the limitations of these procedures in therapy whereas consideration of the often poorly understood underlying physiopathological mechanisms by which the sympathetic nervous system is involved as a component in these various states will be omitted.

In an effort to clarify the matter the various traumatic conditions will be presented under several headings although it is realized that in any given patient the condition may not be a pure one fitting precisely into any one of these categories but may have features common to several of them.

ARTERIAL STUPOR OR SEGMENTAL ARTERIAL SPASM

It has long been recognized that trauma which actually inflicts no direct injury to an artery may initiate a reflex spasm of such degree that blood flow through this vessel may be interrupted with resultant gangrene or ischemic paralysis in certain instances. Specific directives were issued giving proper instructions for the management of this condition. No large group of such cases is available for study. Presumably they were handled in the following manner by periarterial sympathectomy when the artery was exposed in the course of débridement, and in all instances by prompt and repeated use of sympathetic blocks and other efforts to release vasoconstriction until permanent restoration of normal blood flow had been achieved. It is likely that a significant number of cases of segmental arterial spasm involving major arterial stems must have occurred among the thousands of cases of trauma to extremities. The best index of the efficacy of treatment is the fact that only a few instances of ischemic difficulties arising from this condition were seen in the Vascular Centers into which were funneled most of the patients with vascular injuries. These exceptional cases—tragic examples of loss of limb and of function without

direct arterial injury—likewise serve as a stern warning for the necessity of prompt and proper treatment.

From the war experience it would appear that the following points are important in the management of this condition. Physicians must be aware of its existence and trained in its recognition. It must be considered a possibility in any case of injury in which the peripheral pulses in the limb have disappeared with resultant evidence of ischemia, and particularly when there is no significant external bleeding or hematoma and no sign of an arterovenous shunt. It is important that operators be trained to recognize the spastic artery and differentiate it from other conditions following trauma, such as compression by hematoma or intra-arterial thrombosis. In general, the artery will be found to be pale and narrowed in caliber with good pulsation above the area of constriction and with weak or absent pulsation below. Generally there will be no hemorrhage in the artery wall. There will be no firm intra-arterial mass or distention of the lumen, conditions which are commonly observed in embolism or thrombosis.

Once the condition has been diagnosed or is suspected every effort should be made to release vasoconstriction. If the artery is exposed at operation its outer wall should be infiltrated with procaine and it should be carefully stripped of its adventitia. Warning of the body but not of the involved limb should be carried out. A sympathetic block or a spinal anesthesia should be done promptly. If vasodilatation and return of pulsations follow the block or spinal anesthesia but last for only a short while sympathetic blocks should be repeated at frequent intervals. Should the benefit following each block be of short duration, one should not hesitate to proceed with operative sympathectomy or with alcohol block if the patient's condition makes operation ill-advised. The limb itself should be protected from trauma and infection and should be left exposed to room temperature. Local warmth should never be applied unless there is conclusive evidence that one is dealing purely with a remedial condition of arterial spasm without any organic interruption of the continuity

of blood flow. If sustained return of normal blood flow is difficult to achieve promptly and there is no associated injury or disease contraindicating such treatment, anticoagulant therapy should be instituted without delay in order to inhibit thrombosis in the affected artery and in its collaterals.

No data are available as to the incidence of failures in patients who have been treated promptly and adequately; it may be anticipated that success will accompany such a program of treatment.

TRAUMATIC INJURY OF MAJOR ARTERIES

Though they did not constitute a considerable proportion of battle casualties, cases of direct trauma to major arteries presented a difficult therapeutic problem. Odom reported that there were 837 vascular injuries to major arteries among the 92,030 battle casualties sustained by the Third Army during a 9 month campaign in Europe, an incidence of 0.9 per cent. Four hundred and twenty three of the 1833 amputations performed were necessitated by injuries to blood vessels (23 per cent). De Bakey and Simcoe stated that 0.96 per cent of 163,980 battle casualties were wounds of arteries and 618 of the 3177 amputations from the Mediterranean and European Theatres were carried out because of arterial injury (19.5 per cent). In a smaller series of cases, Kirtley found that 20 per cent of major amputations were done because of inadequate blood supply. Bradford and Moore reported that 0.7 per cent of 16,000 surgical admissions to their hospital had injuries of important arteries. It may be concluded that slightly less than 1 of each 100 soldiers wounded in combat sustained an arterial injury and that approximately 20 per cent of all major amputations were performed because of trauma to blood vessels.

Medical officers were instructed by directive to utilize sympathetic blocks in all injuries of major arteries in which the circulation was definitely or questionably jeopardized. The results of this procedure for obvious reasons, are difficult to analyze. The additional therapy in cases of arterial injury was never dependably identical. In some the concomitant vein was ligated while in others it was left intact.

Although ligation and division of the artery were recommended in certain cases ligation in continuity was performed. In some, an effort to maintain the continuity of the blood flow by suture or nonsuture methods was attempted while in the majority no such efforts were made. In most instances adequate control of any attendant shock was promptly accomplished but not in all. There was not uniformity in the application of measures to prevent infection and additional trauma nor in regard to the temperature to which the limb was exposed. Indeed, adequate sympathetic anesthesia was undoubtedly not always obtained by efforts to block the chain of equal import is the fact that sympathetic blocks were carried out as often as necessary in some cases and too few blocks spaced over too wide intervals in others. Of perhaps even greater importance in making evaluation of this procedure difficult is the varying character of the injury incurred.

In order to arrive at valid statistical conclusions one would not only have to segregate treated and untreated cases according to the location of the arterial injury but would have to be certain that the two groups were comparable from the standpoint of the character of the local lesion, the associated trauma and the general state of circulation. Actually the extent of local trauma varied. In certain patients the artery was thrombosed without laceration in others simply lacerated or severed in still others badly damaged over a considerable extent. Sometimes there was extensive local trauma with injury to collateral vessels, extravasation and edema, as well as associated fractures of varying severity or injuries to peripheral nerves. In contrast some patients had no associated lesion of any significant extent. Furthermore in spite of efforts to the contrary case records of patients were often deficient with regard to important factors concerning the character and the extent of the local and general injury and in regard to the therapeutic means employed. It must be remembered too that analysis of the results of sympathetic interruption solely on a basis of the incidence of gangrene necessitating major amputation as is sometimes done omits consideration of possible effects of this treatment upon subsequent

the exercise tolerance was not strikingly altered

The results of sympathetic interruption in cases in which blood flow through a major artery was interrupted by trauma indicated this procedure to be of definite benefit, in my opinion at the same time they clearly demonstrated that this procedure offered no guarantee against ischemic difficulties. With regard to civilian practice I believe the military experience would suggest that every lacerated artery be repaired if this were possible that sympathetic blocks be used promptly and as often as necessary, that when improvement with blocks is only transient permanent sympathectomy be performed by operation if feasible otherwise by alcohol injection. If sympathectomy is not carried out all additional aids in vasodilatation should be utilized such as reflex vasodilatation and the oral administration of alcohol. The limb is to be left exposed to room temperature and to be protected from injury and infection.

It is my impression that early sympathectomy will often prove helpful when procaine blocks are of little permanent help due to their transient benefit. In selected cases seen later after injury sympathetic blocks and more often sympathectomy will be found to be of considerable aid.

ARTERIAL ANEURYSMS AND ARTERIOVENOUS FISTULAS

Before the war sympathectomy or alcoholic infiltration of the sympathetic nerves had been used sufficiently often in cases of aneurysm and arteriovenous fistula to establish its usefulness as an adjuvant in their operative treatment. A number of surgeons during the war had occasion to employ sympathetic blocks or sympathectomy in such cases and held the opinion that they were useful aids. In the three Vascular Centers sympathectomy and sympathetic blocks were utilized in varying degrees. In general, these procedures were not employed at the Ashford General Hospital, and the brilliant results obtained there by Elkin and his associates furnish striking proof that large numbers of patients can be treated successfully without resorting to sympathetic interruption, though those of us who

have studied patients after sympathectomy have been convinced of its usefulness. At the De Witt General Hospital sympathetic interruption was used fairly extensively and was thought to be very helpful in selected cases (11). At the Mayo General Hospital a great many sympathectomies were performed. This experience has permitted me to evaluate the procedure carefully and to formulate certain concepts concerning its benefits and its limitations.

Sympathectomy tends to render the collateral circulation more efficient by elimination of vasoconstriction in the collateral vessels. Though sympathectomy may also contribute to improvement in circulation by fostering growth of new collaterals and though certain observations suggest that this may be true, convincing proof has not been demonstrated. When the collateral circulation appears insufficient according to carefully performed tests when a sufficient time has elapsed to have ordinarily brought about adequate collateral circulation and when such means as intermittent occlusion of the artery appear to be achieving little or no improvement, sympathectomy is indicated. It is also indicated in all cases with poor collateral circulation in which intense pain, infection or threat of rupture make the necessity for early operation a real possibility. In the majority of cases the collateral circulation will be found to be adequate immediately or shortly after sympathectomy. In a number however the tests for collateral circulation may show improvement but may not become adequate over a period of months. Because sympathectomy has been accomplished one can in no sense assume that the collateral circulation will be invariably satisfactory or that gangrene or ischemic paralysis will always be prevented.

Sympathectomy is indicated in any case in which an aneurysm or fistula is associated with a peripheral nerve lesion and in which the collateral circulation is precarious indeed in any case with severe peripheral nerve injury and obviously impaired circulation regardless of whether tests for collateral circulation are satisfactory or not. It appears wise to do everything in these cases to make possible

early surgical treatment of the aneurysm or fistula in order to avoid delay in operating upon the damaged nerves. Occasionally one will find it advisable to perform sympathectomy as a safeguard in cases of vascular lesions of important main stem arteries when the location of the lesion makes accurate compression of the artery and testing of the collateral circulation impossible. It appears rational to perform sympathectomy in those cases with ischemic lesions distal to an aneurysm or fistula. It is indicated when there is significant vasospasm in the affected extremity. The procedure may occasionally be advisable when one or more of the important arteries in a limb have already been ligated or thrombosed and in which cure of aneurysm may entail ligation of other important arteries or collaterals. Sympathectomy may sometimes be required because of associated causalgia.

Sympathectomy need not necessarily be performed before operation the two procedures can often be carried out in one session. In every instance however one should retest the collateral circulation after sympathectomy and make certain that it is satisfactory before proceeding with the surgical treatment of the aneurysm or fistula.

After operation, sympathectomy will also be found to be an adjuvant in correcting certain difficulties which sometimes follow extirpation of an aneurysm or fistula. It is clearly indicated when there is annoying or incapacitating sensitivity of the hand or foot to cold in a patient whose place of residence and work or avocation make such exposure necessary and when improvement in symptoms is noted on exposure to cold during a period of procaine sympathetic anesthesia. It is useful in cases of persistent edema which have not improved upon conservative treatment. It is generally helpful and often dramatically so in cases of ischemic paralysis. It appears to foster return of nerve function in cases of peripheral nerve injury in which the circulation is impaired. It is also useful in the treatment of associated causalgia which is improved temporarily but not cured by sympathetic blocks. When a limb is found to be cold and pale or cyanotic after operation or

when gangrene is definitely threatened, sympathectomy should be utilized in some cases. It brings about gratifying restoration of good circulation though it will not always prevent gangrene. In regard to the two commonest circulatory disorders which may follow sympathectomy sensitivity of the limb to cold and decrease in exercise tolerance, the procedure has a very beneficial effect upon the former but rarely has a striking effect upon the latter.

It is my feeling that when sympathetic interruption appears to be indicated, permanent sympathectomy is generally preferable to procaine blocks, though blocks undoubtedly have a place in the treatment of certain cases. Sympathetic interruption seems justified for the indications which have been enumerated where no clear indication exists there seems to be no point in performing the procedure. It must be looked upon as a valuable adjuvant in the surgical treatment of aneurysms and fistulas. It cannot be relied upon as a certain guarantee against ischemic difficulties, nor can it be relied upon as a sure corrective for all functional disorders which may be present.

To have performed a sympathectomy does not relieve the surgeon of responsibility for utilizing carefully performed tests for collateral circulation for exercising every care to prevent destruction of collateral vessels at the time of operation and for preserving the continuity of the artery if possible.

THE POSTTRAUMATIC DISORDERS

The posttraumatic vasomotor disorders comprise a number of conditions about which many divergent opinions are held. Some would include only those cases with edema, pain, weakness, disability, atrophy, osteoporosis, and either vasoconstriction or vasodilatation. Others would include in this category various vasomotor disturbances following trauma, infection and such vascular disorders as thrombophlebitis. The discussion here will be limited to the difficulties following trauma or to trauma and associated infection. It has been my experience that these disorders may be characterized by various complaints and physical findings. In some

pain is present either at rest or more commonly with activity and weight bearing in others pain is absent. In some edema is massive, in others moderate or mild, and some have no edema at all. Some have evidence of vasodilatation the majority of vasoconstriction. Cyanosis, coldness sensitivity of the part to cold and hyperhidrosis may be present in varying degree. Some have marked weakness of muscles some virtual paralysis. Sensory changes may be present.

In a group of disorders so varied in their manifestations there is little wonder that treatment cannot be stereotyped and that results of therapy are not uniform. Those who have utilized sympathetic blocks and sympathectomy have been favorably impressed with the results of such treatment (32) as have my associates and I. It is not my feeling that such treatment should invariably be applied or that it can ever be utilized as the sole means of therapy. It is difficult to outline concisely one's views of treatment for such a complex problem but to do so as succinctly as possible the following suggestions are made.

In any case of trauma which is unassociated with injuries contraindicating such treatment early active use of the part should be instituted. Obviously wounds must be debrided fractures properly reduced and immobilized and every precaution taken to prevent infection. Whenever edema is present proper elastic support, elevation and gradually increasing use of the limb in dependency should be utilized. One must be sure to encourage the patient and to do everything to prevent development of an attitude of invalidism. If a real neuropsychiatric factor exists, it must be recognized and suitable treatment instituted.

Whenever there are signs or symptoms suggesting a reflex disturbance such as is under consideration and these manifestations prevent active use of the limb or do not improve rapidly with such activity and with proper associated treatment, sympathetic blocks should be tried without delay and should be repeated as frequently and as often as necessary. If they bring about transient improvement but appear to have no permanent

benefit, one should not hesitate to proceed with sympathectomy. In certain cases it will be preferable to employ local procaine infiltration first before performing sympathetic blocks. If such local infiltration brings about temporary benefit but no cumulative improvement and an irritable trigger zone seems to exist which can feasibly be excised such a procedure may be indicated. In connection with local infiltration it is proper to introduce here the technique of procainization in the early treatment of sprains and strains which was found very effective in army personnel (20). That at least part of this benefit results from blocking the sympathetic impulses is suggested by the fact that such injuries have been treated with equal success by sympathetic blocks (32).

In the treatment of the late sequelae we have found that many patients obtain an excellent result from active use of the limb physiotherapy and elastic support when needed. It was found that in a small number of patients manifestations very similar to those generally observed were either initiated or perpetuated by neuropsychiatric factors. In such cases psychiatric therapy is obviously required. In some a brilliant result is quickly achieved others are very refractory. In rare cases responding unsatisfactorily to psychiatric treatment, sympathetic interruption may be a useful adjuvant in correcting certain manifestations such as persistent massive edema. When the simpler means of treatment show no promise sympathetic blocks should be carried out. Occasionally a patient is helped decidedly by blocks but ordinarily any beneficial effect is transitory. In general sympathectomy is the procedure of choice for such cases. Except for cases in which a fundamental psychiatric problem has been unrecognized before operation, the results are gratifying. The manifestations of vasospasm and sympathetic overactivity respond dramatically cyanosis, coldness hyperhidrosis are relieved and sensitivity to cold is cured or improved. Edema is generally lessened sometimes dramatically. Pain is generally improved and is sometimes completely eliminated. Sympathetic interruption can never be regarded however as the sole

form of treatment. Whether it is used or not, the patient must be encouraged active exercise must be enforced and edema must be dealt with by elastic support, rest, and gradually increasing dependency.

No data have been made available in regard to possible usefulness of sympathetic interruption in the healing of fractures. It has been demonstrated however that sympathectomy may be extremely useful in reducing edema and in eliminating marked vasospasm before bone grafting and other plastic restorative procedures.

CAUSALGIA

The war afforded an unparalleled opportunity for studying large numbers of cases of causalgia and their treatment (2, 12, 18, 24, 31, 33). In general excellent results from sympathectomy were obtained. The majority of patients obtained complete relief and improvement was almost invariably noted in the remainder. It has been the common observation that the results were better in the upper extremity than in the lower. Certain observations suggest that the poorer results in the lower extremity may be due in part to incompleteness of the ganglionectomy—that it may be necessary to sympathectomize completely the area of the nerve lesion as well as that to which the pain is referred (2, 33). The series of Rasmussen and Friedman suggests that postganglionic operations for the upper extremity are inferior to the commonly employed preganglionic operation in the treatment of causalgia. Although such observations have not been uniformly made it has been my experience that the more severe the pain the more apt one is to obtain complete relief following sympathectomy. Since the pain is generally more severe in the upper extremities this may be an additional factor in the somewhat higher incidence of complete cures in these cases as contrasted with those having involvement of the lower extremities. In general it is thought that the results are more favorable the earlier treatment is instituted.

Some surgeons have utilized sympathetic blocks only as diagnostic and prognostic tests and some (33) have never obtained permanent

relief from any number of procaine sympathetic blocks. Though we found that sympathectomy was necessary in the majority of cases, my associates and I observed permanent relief from sympathetic blocks in numerous instances. It is our feeling that one should proceed with sympathectomy if relief of pain is limited to the period of sympathetic block and that a series of blocks should be tried: patients who experience prolonged relief after a procaine block. If the relief does not become progressively more prolonged as additional blocks are carried out, they should be abandoned and operation should be carried on. It is apparent from the experience in the war that a rare patient with causalgia may be cured by neurolysis or neurotomy or by artificial fever therapy. A rare case, too, may be associated with definite neuropsychiatric features and respond favorably to psychiatric therapy (16). In general, however, sympathectomy is required. Altogether the results are brilliant.

PHANTOM LIMB PAIN AND AMPUTATION STUMP PAIN

Few wartime observations have come to my attention concerning the use of sympathetic interruption in the distressing phantom limb syndrome and in amputation stump pain. To be sure, a few cases of pain and vasospasm in minor amputation stumps with improvement or relief following sympathectomy have been recorded (12) and I have made similar observations. In addition, Pool has used sympathectomy in conjunction with cordotomy in a few cases of phantom limb pain and has the impression that sympathectomy may be helpful in relieving the burning pain seen in this syndrome. In general, however, no studies have been made of sympathetic interruption in the complex amputation stump pain following major amputations nor in the phantom limb syndrome—in all likelihood a reflection of the infrequency with which these difficulties have occurred in military personnel. I believe the primary lesson to be learned from the experience in the recent war deals not with the treatment of amputation stump pain and phantom limb pain but with their prevention by proper operative technique, by early active

use of the stump and by careful conditioning of amputees to the normal physiological sensations of a phantom limb which they almost invariably experience (19). I have had occasion to observe in patients in whom such procedures were performed for other reasons that the normal phantom limb sensations may be temporarily but not permanently relieved both by sympathetic blocks and by sympathectomy. My own small experience would lead me to believe that sympathectomy rarely has a place in the treatment of amputation stump and phantom limb pain.

THE INJURIES DUE TO COLD

Opinions are at wide variance in regard to the rôle of sympathetic interruption in the injuries due to cold—frostbite, trench foot, and immersion foot or band. Elsewhere (28) I have attempted to review this subject. It appears clear that although other factors may have a part, thrombosis of arteries and arterioles is the primary factor concerned in the production of gangrene—the most disastrous sequel to injuries from cold. It is further well established that vasoconstriction is the primary response of the body to exposure to cold, and that, although a transient period of reactive hyperemia may follow vasoconstriction is one of the commonest sequela. These facts would suggest that efforts to block sympathetic impulses and combat vasospasm might be fruitful in the treatment of the acute and later manifestations of these disorders.

Numerous students have advised against sympathetic interruption in the early stages of trench foot, immersion foot, and frostbite, perhaps on insecure grounds. There is little information from our own war experiences concerning the effect of these procedures in the early treatment of frostbite although some of our allies and opponents reported good results with sympathetic blocks and periaxillary sympathectomy. Davis and associates, who felt that it was important to release vasoconstriction as rapidly as possible, found that direct blocking of the sympathetic pathways was the only means of accomplishing this end in severe high altitude frostbite. Southworth has treated a few cases of early frostbite by sympathetic blocks with apparent

benefit. Berson and Angelucci noted no improvement with sympathetic blocks in a few early cases of trench foot with massive edema, but obtained temporary diminution of pain and tenderness in milder cases. Leigh reported that sympathetic blocks were of no aid in the early treatment of trench foot. Edwards and his co-workers in a small group of cases, found that sympathectomy gave good results in the early treatment of trench foot with gangrene but that it was not helpful in cases with tender painful and aching feet. No studies have come to my attention concerning the use of sympathetic interruption in the treatment of the acute phases of the immersion injuries.

With regard to treatment of late manifestations of these disorders, the rôle of sympathetic interruption has been more clearly defined. The results of sympathectomy are good in properly selected cases of frostbite. The procedure is useful in cases of gangrene, excessive hyperhidrosis, persistent marked vasospasm, sensitivity of the hand or foot to cold and sensory changes. Southworth reported some observations suggesting that repeated procaine blocks, alcohol blocks, or sympathectomy may be helpful. Berson and Angelucci reported that sympathetic blocks were useful in late cases of trench foot with vasospasm, and that the improvement in treated limbs was faster than in the non-treated contralateral extremities. Although my associates and I were not impressed with the usefulness of sympathetic blocks in the late treatment of trench foot, we obtained conclusive evidence of the benefit of sympathectomy in selected cases. Sympathectomy unfortunately rarely is of aid in alleviating the pain which is so commonly experienced on weight bearing. It is particularly helpful in cases of gangrene, in marked hyperhidrosis, especially if associated with maceration of the skin and secondary infection in reducing the severity of symptoms in patients with sensitivity of the extremity to cold and in certain cases in which there is disturbance of sensation. Patterson found that sympathetic blocks improved temporarily the peripheral pulses, decreased numbness and pain, and abolished hyperhidrosis in the Attu casualties,

but observed that the beneficial effect was limited to the duration of sympathetic anesthesia. Southworth felt that sympathectomy produced beneficial effect upon the late manifestations of immersion foot although it had little effect upon deep pain.

Because such contradictory opinions are held by different observers it is exceedingly difficult to summarize any lessons which may have been learned in the recent war concerning sympathetic interruption in the treatment of the early stages of the injuries due to cold. I think it is fair to say that at least no harm has resulted from the use of such procedures and that their use for further evaluation is warranted. There is much to suggest that they may be very helpful especially if applied early and particularly in cases in which gangrene is threatened or existent. It is my feeling that if transient improvement without permanent benefit is noted following blocks, especially in cases with marked ischemia, one should seriously consider early sympathectomy. With regard to the later stages of these injuries, it is clear that sympathectomy has a definite though limited place in therapy. Though repeated sympathetic blocks may occasionally result in benefit, sympathectomy is generally required. Sympathetic interruption cannot be looked upon in any case as the sole means of therapy. One must, under all circumstances, protect the injured limb from trauma, infection and from external heat in the acute phase. There is much to suggest that anticoagulants should be employed in early cases. Conservatism should be practiced with regard to gangrene and necessary amputations. Physiotherapy and active exercise should be utilized after the acute phase is passed. Shoe corrections, psychotherapy and other means should be used when indicated. It is my opinion that further experiences will confirm the usefulness of sympathetic interruption in alleviating certain complaints late in the course of these disorders and that they may well prove of value in the early stages.

SUMMARY AND CONCLUSIONS

The experiences during the recent war have in general confirmed pre-existing impressions concerning the usefulness of sympathetic

interruption in cases of trauma and in the posttraumatic states. Certain new applications of these procedures have been established. The war experiences have been particularly valuable in providing large numbers of cases for study with consequent better evaluation of the specific indications, the merits and the limitations of sympathetic interruption. It would seem that permanent sympathetic interruption may yield gratifying results in some instances in which previous blocks give unsatisfactory results. With regard to certain types of injury there are differences of opinion concerning the usefulness of these procedures. In the presentation of this problem an effort has been made to take into consideration the studies of various investigators, though the views expressed concerning controversial issues have necessarily been influenced by personal experiences.

THE TRANSPORTATION OF SOLDIERS WITH FRACTURES

WILLIAM J STEWART MD., F.A.C.S., Columbia, Missouri

THE transportation of a soldier with one or more fractures usually compounded was one of the major medical problems encountered in the European Theater of Operations. In general most of the patients, immediately after wounding were transported by ambulance from the aid stations to the forward hospitals and then by train boat or airplane to the rear echelon hospitals.

The past standard practices of transporting patients with fractures recommended by the Army Medical Corps were reviewed by the consultants and somewhat modified before the advent of major hostilities on the continent. The major modification was made in regard to the transportation of fractures of the upper extremities.

Almost everyone consulted agreed that the Murray Jones arm splint was an awkward device to apply and it was felt by most doctors that this awkwardness, combined with certain dangers of excessive pressure in the axilla offset any good factors about the splint. Accordingly the medical officers were not encouraged to use it. Most upper extremity injuries were very simply and easily handled by simply binding the affected arm to the trunk with a sufficient number of triangular bandages. This provided good comfortable immobilization and obviated the necessity of applying a cumbersome piece of apparatus. In addition transportation by litter in an ambulance was a much simpler procedure than it would have been if this splint had been used widely.

Upon arrival at a field or evacuation hospital, or any hospital where surgery on the injured upper extremity was performed a plaster velpeau or modified plaster shoulder spica dressing was applied after surgery and was termed a transportation plaster splint for the next stage in the evacuation of the patient.

This splint was either removed and the wound was inspected and the splint then was reapplied or else it was left intact by successive medical officers in the line of evacuation, according to their best judgment. Eventually the patient reached a general hospital where he was to be hospitalized for the next stage in his treatment. At this hospital the "transportation plaster" was removed and appropriate therapy usually skeletal traction was instituted to care for the fracture.

The first splint applied for the transportation of fractures of the long bones of the lower extremity was almost universally the army half ring splint. This was applied at the forward dressing station and remained in place until the patient was received at the field or evacuation hospital for his initial definitive therapy. The ambulance drivers and others responsible for his care during transportation from the aid station to the forward hospital were instructed to release the traction provided by the army hitch which was, in most instances, applied over the patient's shoe of the affected extremity. In the event the foot had been injured together with the long bones of the lower extremity the extremity was simply held in place in the half ring splint by means of triangular bandages, usually five in number and no attempt was made to apply traction. I observed a few individuals arriving at evacuation hospitals who had had undue pressure caused by the army hitch, or who had had the hitch in place many hours without release, but I cannot recall a single instance where any permanent damage was done by this procedure. I was favorably impressed by the comfort with which most soldiers with extensive fractures were transported from forward aid stations to evacuation hospitals in the army half ring splint.

After initial definitive treatment—definitive treatment, etc.—at the field or evacuation hospital, these patients, for the most part were encased in one and one-half plaster hip spicas for a

single extremity, or double spicas when both legs were involved and removed to the next hospital in the line of evacuation. These spicas were very well padded affairs. Plaster and padding were split and cut down to the skin throughout the entire length of the extremity up to the hip joint on the affected side. The legs of the plaster were joined with one or more plaster ropes or wooden struts to provide for stability. The patients who were received at rear echelon hospitals in all of these transportation plasters both for the upper and lower extremities, were for the most part remarkably comfortable. Shock was minimized, pain was not an outstanding complaint, and dressings over the operative areas were retained in place, requiring minimal attention and inspection.

Before the advent of major hostilities in Europe the American Army Medical Corps was given the experience of the British in regard to transportation plasters. The British recommended the use of a hanging plaster for fractures above the elbow joint and the use of Tobruk splints for lower extremity injuries.

The hanging plaster was found by most American medical officers to be unsuitable because it did not immobilize the fracture during a long rough ride on a litter in an ambulance. Most patients complained of pain. The Tobruk splint was not regarded favorably by American medical officers because of the lack of immobilization of a fracture of a femur unless it happened to be just at, or immediately above, the knee joint, and because of the constant pain the patient experienced.

I myself tried on many occasions to demonstrate a Tobruk splint to American medical officers and had a most difficult time applying it, much more trouble in fact than was experienced in applying the large one and one half or double plaster transportation hip spica.

There were many modifications of the Tobruk splint but, in general it consisted of adhesive traction straps applied to the skin along the full length of the extremity with padding over the malleoli.

1 An overlying snugly applied long leg plaster splint encasing the foot to provide support and minimize rotation of the extremity.

3 Slots in this plaster in the region of the malleoli through which the traction straps were passed.

4. An army half ring splint supporting the whole extremity in plaster with the traction straps tied over its end.

5 The incorporation of a windlass arrangement in these straps theoretically to provide skin traction to the injured extremity.

Undoubtedly, the British transportation plasters, namely the hanging plaster and Tobruk splint, used less material than did the American army spicas and velpeaus, and also could be applied with the aid of less personnel but the patients were definitely not as comfortable as in the American devices. The British medical units had less material and fewer personnel than did the American counterparts and it is my own feeling that these transportation splints were developed to meet the material and personnel shortages of the British Army.

The Tobruk splint was used upon occasions by American medical officers and an attempt was made by one of the army consultants Lieutenant Colonel John Manning to follow up all of these cases in the Ninth Army. The number of cases that he was able to contact was nowhere near as impressive as the British figures but the conclusions reached by Lieutenant Colonel Manning substantiated the general belief that (1) There was no uniformity in the types of splints used (2) the transportation of such patients was accomplished with much more pain and discomfort than those encased in plaster spicas (3) the probability of retaining dressings in place in the upper thigh was much more difficult than when a spica was used.

Translating these lessons to civilian life it seems to me perfectly logical to recommend the abandonment of the use of the Murray Jones arm splint as a first aid appliance. I believe civilian patients can have upper extremities particularly when the humerus is involved bound rather snugly to the trunk by gauze or elastic bandages and can be transported in comfort. I should certainly recommend the use of a plaster velpeau type of dressing if a compounding wound has been suffered which has been debrided or closed in

a patient who must be transferred to some other hospital for long term care. When civilian injuries involving the long bones of the lower extremities are encountered the army half ring splint with foot piece and army hitch reasonably well padded over the dorsum of the foot provides an excellent device for transportation. In the event a compounding wound has been encountered which has been debrided or closed a well padded plaster spica applied to the extremity without regard to the problem of reduction of the fracture serves as an excellent transportation device.

CONCLUSIONS

1. The Murray Jones arm splint was felt to be cumbersome and difficult to apply. Much more comfortable and efficient immobilization

was obtained by binding the injured upper extremity to the patient's trunk.

2. The plaster velpen and modified shoulder spicas were preferred to hanging plasters in transporting patients after initial surgery.

3. The army half ring splint with army hitch is an excellent device for transporting fractures of the lower extremity.

4. One and one-half or double hip spica plasters are recommended after initial surgery and are much to be preferred to the British transportation devices labelled Tobruk splints.

5. The above devices, consisting of patient body immobilization plaster velpens & shoulder spicas, army half ring splints with foot rest and army clove hitch, and plaster transportation spicas can well be recommended for civilian use.

PENICILLIN IN EXPERIMENTAL INTESTINAL OBSTRUCTION

A Summary of Observations with Reference to Their Clinical Application

ALEXANDER BLAIN III M D Ann Arbor Michigan

THE mechanism of death in intestinal obstruction is only poorly understood. Previously death in all types of obstruction was ascribed to a tox

It is now known that the vomiting associated with high obstructions produces profound chemical changes in the body and that these may be alleviated by the parenteral administration of salt and water. The studies of Wangenstein and others have shown that the relief of intestinal distention does much to reduce associated shock and the hazards of operative intervention. In spite of the advances of recent years in the management of bowel obstructions we still find 1 patient out of every 5 or 6 dying after operation for acute mechanical obstruction of the small bowel (5).

It is thus obvious that more must be learned concerning the pathology of intestinal obstructions in order that new surgical adjuncts can be developed to diminish the hazards associated with such lesions.

When penicillin became available for experimental purposes, we were given the opportunity to restudy certain phases of the intestinal obstruction problem. The factors of bacterial infection and toxemia in the pathogenesis of death from experimental obstruction particularly were reinvestigated.

It is the purpose of this report to summarize our studies on the effect of penicillin in experimental types of intestinal obstruction and to show why the conclusions reached demand

new clinical emphasis on the phases of the problem which were investigated.

PENICILLIN IN ISOLATED LOOP EXPERIMENTS

Prior to our experiments with penicillin in closed obstructed intestinal loops (12) it was known that animals with such lesions would die usually within a week after the creation of the loops in a manner which could best be explained on the basis of a toxemia. The pioneer studies of Stone, Bernheim and Whipple had demonstrated that death in such experiments could not be explained on a basis of vomiting and that septicemia was not a factor. The numerous experiments to prove or disprove the elaboration of toxic substances within isolated loops have been critically reviewed by Cooper (1928), Morton (1929) and Besser (1940). Some investigators, notably Davis and Stone, Murphy and Brooks, Dragstedt and Firor (10) believed that lethal toxins did develop in isolated loop experiments and furthermore that the source of these toxins was bacterial. This latter belief was based on a process of exclusion as there was no positive way to rule out sources other than bacteria for the production of toxins.

In Dragstedt's experiments the isolated loops were washed with ether. The dogs having washed loops survived much longer than did the controls. The possibility was never ruled out in his experiments that the ether might alter the loop mucosa thus interfering with the absorption of toxins of any origin. Firor (10) demonstrated with U shaped loops having both ends open at the surface of the dog's abdominal wall so that periodic through and through cleansing with saline solution could be accomplished that life was prolonged for considerable periods of time after the loops

From the Departments of Surgery and Pathology of the Johns Hopkins University and the Johns Hopkins Hospital.

Dr. Blain was formerly William Stewart Halsted Fellow in Surgery, The Johns Hopkins Hospital, now Resident Surgeon, The University Hospital, Ann Arbor, Michigan.

Presented in the forum on Fundamental Surgical Problems, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Fig. Occlusion of bowel lumen by transection just above termination of antimesenteric artery of ileum and closure of proximal and distal ends.

were finally closed. The fact that in his experiments the animals eventually died of inanition obscured the mechanism of death in these experiments but again suggested the elaboration of lethal toxins of bacterial origin.

Firor's original suggestion (11) that a modern chemotherapeutic agent (sulfasuxidine) be employed in isolated loop experiments, was, I believe, the greatest contribution to the study of intestinal obstruction since the introduction of the Miller Abbott tube by Abbott and Johnston. Firor and Poth (11) demonstrated that sulfasuxidine when placed in closed isolated loops, would protect animals with such obstructions for long periods of time. The work was confirmed (13). We had one such animal which was sacrificed over a year after operation. The objection to the sulfasuxidine experiments was that the mucosa was altered

by being covered with a thick paste which could theoretically have interfered with the absorption of toxins of any origin. The observations of Firor and Poth led to the important studies of Sarnoff and Poth (18) and Sarnoff and Fine (19) who reported that sulfasuxidine had a protective effect in dogs with ileal lesions, produced by occlusion of the mesenteric veins, but in which the bowel lumen was unobstructed. Their studies established the important rôle played by bacteria in such lesions, but showed that sulfasuxidine must be present for some time for effective bacterial depopulation of the bowel to occur.

In 1945 it was shown (12) with the use of penicillin either placed in isolated loops or administered parenterally in dogs having isolated loops, that bacteria or bacterial products were responsible for the death of animals in such experiments. Furthermore, the lives of dogs having isolated obstructed jejunal loops could be prolonged for significant periods of time when penicillin was placed in the loops or was given intramuscularly. Thus, in 100 per cent of 15 control dogs with isolated jejunal loops, death occurred within 6½ days. 87 per cent died in 3½ days or less. In 100 per cent of 15 dogs, in whose isolated loops penicillin was placed, protection was afforded for 9 days, in 93 per cent for 13 days and in 60 per cent for over a month. One hundred per cent of 5 dogs treated parenterally with penicillin were protected for over 18 days. One dog lived over 2 months.

It was widely held at that time that penicillin was not effective against the gram-negative bacilli. This study demonstrated that for all practical purposes, penicillin in large doses was effective *in vivo* against all of the intestinal tract bacteria.

It was found that marked distention of the loop occurring in the presence of bacteremostatic agents was compatible with life. In the absence of distention of the loop, an abundance of bacterial flora uninhibited by bacteremostatic agents was compatible with life. The experiments indicated that distention must be present before infection of the intestinal wall by the normal intestinal flora can occur. Microscopic and bacteriological evidence was presented to show that penicillin given prophylactically

Fig. 2. Method of tying off mesenteric veins to ileal segment. a, Proximal turned in end b, distal turned in end c, rent in mesentery at distal extremity of segment to be strangulated. (Courtesy *Bull Johns Hopkins Hosp*)

lactically in large doses, whether in a loop or parenterally can prevent infection of the distended intestinal wall by the normal intestinal flora. Recently in experiments employing streptomycin in rabbits with closed loops (created by tying off the base of the large appendix) a similar protective action was demonstrated (9).

PENICILLIN IN STRANGULATED LOW ILEAL OBSTRUCTION

In an attempt to produce an obstruction more like that occurring in man and to test a treatment which might be effective for a similar type of obstruction in man Dr John D. Kennedy and the author (3) created strangulated low ileal obstruction in dogs by first completely occluding the bowel lumen (Fig. 1) and then tying off the mesenteric veins to a 60 centimeter segment of the obstructed bowel (Fig. 2). The resulting obstructions were characterized by severe strangulation (Fig. 3). The control dogs' intestines all showed mucosal ulceration and massive bacterial invasion superimposed on the venous infarction which would often be accompanied by perforation. In the first 24 hours following

the production of such lesions there would not always be peritonitis unless perforation had occurred. Later peritonitis developed whether or not there was perforation. The lesions in

Fig. 3. Strangulated low ileal obstruction showing gross appearance of the resulting hemorrhagic infarction of the bowel wall. The proximal turned-in end is in center of photograph. In this particular case this lesion was resected 72 hours after its production in a dog treated with massive doses of penicillin. The animal was cured.

Chart. Diagram showing relative survival times of dogs with strangulated ileal obstructions not treated with penicillin as contrasted with the survival times of dogs with strangulated ileal obstructions treated with penicillin. It can be seen that 4 of the 5 penicillin treated dogs having late resections of their strangulated obstructions were

cured. Both groups were treated equally for hemorrhagic shock, chloride and water loss. Black, postoperative survival time of control dogs with strangulated ileal obstructions. Cross hatch, postoperative survival time of dogs with strangulated ileal obstructions, given massive doses of penicillin parenterally. Black dot, cures.

similar experimental obstructions which had been treated with massive doses of penicillin (100,000 units every 2 hours for 24 hours, 50,000 units every 2 hours during the next 48 hours, and 50,000 units every 4 hours during the remainder of the survival of these dogs whose weight averaged less than 16 kilo-

grams) always showed a well marked bacterial invasion microscopically, but this was appreciably less than that which occurred in the controls.

Thirteen dogs, with this type of obstruction treated with whole blood and gelatin solution intravenously and with physiological

saline solution subcutaneously to combat hemorrhage, shock, chloride and water loss died within 36 hours. Seven dogs treated similarly but with massive doses of penicillin in addition survived between 50 and 100 hours (Chart 1). Six dogs lived 70 hours or longer 4 90 hours or longer. In addition in 2 other penicillin treated dogs resection of the strangulated obstructed bowel was performed at 72 hours (a period twice the survival of any control dog) with a cure in each animal. Later in 3 more penicillin treated dogs, resections were carried out at 72 hours, with cure in 2 of the 3 dogs. Thus, there were 5 late resections performed at a time which was twice as long as any dog not treated with penicillin lived. Four of the dogs in which late resections were performed were cured. Drs. Robert J. Calihan and Henry N. Harkins aided us in these latter experiments and we reported the resection experiments with them (4).

In all cases, the control dogs and the dogs treated with penicillin were treated with equal vigor for shock, hemorrhage, chloride and water loss. In 2 of the penicillin treated dogs and 1 of the controls, volvulus of the strangulated bowel converted simple strangulated obstructions into strangulated closed loop obstructions. Thus it was demonstrated that penicillin in the doses employed (which were massive) in the study, could prolong the lives of experimental animals having the type of strangulated obstruction chosen for the study. It was also demonstrated that this prolongation though striking was limited. Whether the limit was set by (1) the final inability of the penicillin in the doses employed to control bacterial infection (2) fatal alterations in metabolic processes and body chemistry (the serum NPN, phosphorus and potassium were elevated, the sodium and chloride were normal to high and the carbon dioxide combining power was low) (3) the presence within the peritoneal cavity of necrotic strangulated bowel, or (4) some combination of these factors, could not be definitely established on the basis of this study. Because of the effect of penicillin in experiments with nonstrangulated closed loops, however, it would appear that the effect of penicillin would be much more striking in obstruction in which the de-

gree or amount of strangulation was less marked.

These studies demonstrated that bacteria play an important rôle in the 'toxemia' and death in dogs with strangulated ileal obstructions and that aggressive antibacterial therapy in the form of frequent, massive doses of penicillin is effective to a significant extent in treating such lesions.

THE FIELD FOR PENICILLIN THERAPY IN HUMAN INTESTINAL OBSTRUCTION

In a study of 204 cases of acute complete mechanical obstruction of the small bowel, in which patients were operated upon at the Johns Hopkins Hospital during the 10-year period 1936-1945 there was an overall mortality of 20 per cent (5). When this mortality rate was corrected for deaths due to cardiac, pulmonary, and other causes not directly related to the intestinal obstruction the mortality rate was 15 per cent. Of the 41 deaths in the series, over half were due to peritonitis. In 27 per cent of all cases the bowel was strangulated at operation. In an additional 5 cases although the bowel was considered viable by the surgeon at operation gangrene and necrosis were found at autopsy. The strangulated cases accounted for over half of all the deaths due to peritonitis. The study confirmed the statement of McKittrick and Sarris that 'the factor of strangulation is the greatest single factor determining the outcome of a case of intestinal obstruction' and showed that there is a fertile field for an adjunct against bacterial infection in intestinal obstruction. Indeed it would seem that no further great reduction in the present mortality rate can be made until bacterial infection and 'toxemia' are combated.

DISCUSSION

Evidence has been presented which demonstrates the important rôle played by bacteria in death resulting from the types of obstruction studied. Furthermore it has been shown that the lethal effects of bacterial growth can be significantly obviated by massive doses of penicillin. It should be stated here that the exact mechanism by which bacteria produced their lethal effects in our experiments is not

clear. We feel that the ascribing of all deaths in experiments of this nature to peritonitis is an over-simplification of the problem (14). At any rate it would seem that the beneficial results of penicillin therapy noted in our experimental animals, could be applied directly to man. Human studies have revealed that the problems of strangulation and infection are grave ones and also that the presence of strangulation is often impossible to diagnose, especially in patients with early cases short of direct visualization of the affected bowel wall.

When these factors are combated in experimental animals life is prolonged and significant protection is afforded.

CONCLUSIONS

1. A clinical trial of massive antibacterial therapy for acute mechanical small bowel obstruction in man is warranted.

2. It is believed that such a trial would significantly lower the present intestinal obstruction mortality.

3. Penicillin should be regarded as an adjunct to early and adequate surgical intervention in acute obstruction and not as a means to delay operation.

MAJOR AMPUTATIONS

RUFUS H ALLDREDGE M D F A.C.S New Orleans, Louisiana

THE changes which have come about in the surgical treatment of amputations due to the recent war effort and which are adaptable to use in civilian life have been chiefly the result of good planning and organization for the care of these cases. The early establishment of the use of sound surgical principles and practices for the early and immediate care and transportation of war amputations and implementation of these policies by authoritative directives was an important part of this planning. This together with the establishment and organization of special centers for definitive care and rehabilitation contributed more than anything else to whatever changes for the better there may have been in surgical treatment. The modern advances in medicine, medical education and graduate education played the rôle of making a higher standard of practice of medicine and surgery available, but all these would have amounted to very little had it not been for proper organization (5). This brought the patients together under the direction of highly specialized surgeons who had the responsibility for not only organizing the whole functioning of the center with all its different departments but for all of the complete care of the whole patient and all of his problems. Even here in the amputation centers the value of organization could hardly be overestimated. For truly surgery is not the end but one of many means to the end in this field. Besides organization it was chiefly due to the fact that the surgeons were in complete charge of all of the amputee's problems from the time of his amputation until he was fitted with a limb and trained to use it that better surgery was done with better results than ever before (1).

These are the important lessons learned from the War and herein lie the hints for the wise if service is to be improved for civilians in the future. It is of course impossible and

unnecessary to duplicate the war services in civil life but it would be a simple matter indeed to establish organized amputation services in the larger civilian hospitals, just as fracture and other special services were developed in the past. The management of amputations would then improve just as fracture treatment has. There is no obvious reason why existing limb makers could not co-operate completely with the surgeons in this matter just as brace makers always have. There can be no quarrel between surgeons and limb makers. The ultimate aim of both should be to give the patient the best possible care. If either or both fail in this important task they may find someone else doing their work for them. For if something is not done to improve the care of civilian amputees the federal agencies may justifiably take over the whole problem including especially the manufacture and fitting of artificial limbs.

SURGERY

The strongest trend in the surgery of amputations has been toward more conservatism. This has been true both in the immediate surgical treatment and in the definitive surgery. The general use of the modified guillotine amputation at the lowest possible level resulted in the saving of more of the limb than ever before in war or civil life both at the time of primary amputation and finally when definitive surgery was done. The more complete understanding of the problem of the amputation stump in its relation to the prosthesis by the surgeons has resulted in a more conservative surgical attitude with a marked tendency to leave as much stump length as possible and to fit the remaining stump with a prosthesis regardless of its length. The chief exception to this is amputations below the knee of more than 7 inches in length. One of the truly great lessons learned was that the problems of the surgery of the stump are so closely related to those of the prosthesis that it is impossible to completely understand one without under

Presented at the symposium on Fractures before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

standing the other and that they cannot be separated from one another. Since the surgeon is the only one who can understand all of the problems, particularly these two, he is the only one who is or ever will be qualified to properly supervise and direct the whole care of the amputation stump and the patient.

The important changes that have come about in the surgical treatment of amputations, then, have not been due to the development of new operations, techniques, or methods. Rather they are due to organization, good judgment, good surgery, and most important, the complete responsibility of surgeons for the whole patient and all of his problems. The problem is an arduous one and nothing has been found which will take the place of hard work and the greatest attention to details.

1. *The open or modified guillotine amputation.* The routine use of this method of amputation in the United States Army has again proved to be the safest and best method for use in war notwithstanding some opinions to the contrary. Although long skin flaps which tend to close the wound prematurely are undesirable, it is important that viable skin be conserved at least equal in length to the bone. The use of the modified guillotine amputation at the lowest level consistent with proper débridement without regard to the final site of amputation with proper skin traction until the stump is ready for final revision or reamputation has proved to be of such great value in the war that it must find greater use in contaminated civilian cases. The stump is ready for revision or reamputation in from 3 to 8 weeks post-operatively depending upon the case. Reamputation at a higher level when indicated can be done much earlier than revision at or near the stump end. This is one of the reasons why the original open amputation should be done at the lowest possible level. The stump is ready for revision when the skin has been pulled well down over the stump end, drainage has ceased, swelling has subsided and the remaining open wound is clean. Routine bacteriological examination of the stump wound is advisable before the final operation is done. It is not necessary or desirable in the majority of cases to wait for complete healing to take place (6).

The use of skin grafts on amputation stumps is mentioned only to be condemned. They are distinctly disadvantageous in that they stop the whole normal healing process and they are poor substitutes for the normal skin which can easily be drawn down over the stump-end by traction. When skin grafts are used they interfere with the function of the stump in the prostheses by breaking down to such an extent that they should routinely be removed and traction applied until the skin can be closed. The removal of skin grafts from stumps for use elsewhere is equally to be condemned as the donor area causes difficulty when the prosthesis is applied.

2. *Essential points in amputation.* (a) The operation should be done with the use of a tourniquet whenever possible. The use of the tourniquet can be extended by the use of Wyeth pins on short thigh stumps.

b. Definitive operation should be done in a clean field and under careful aseptic precautions.

c. Except in end bearing stumps, the skin flaps should be cut equal in length so that they meet in the center of the end of the stump without redundancy. A general rule for estimation of the length of the skin flaps is to cut each flap approximately two-thirds of the length of the radius of the limb. The stretching of the flaps, which then results after under cutting, permits them to lengthen sufficiently for closure.

d. The deep layer of fascia is reflected with the skin flap in primary amputation whenever possible. The muscles are divided slightly distal to the saw line so that after retraction has taken place the end of the muscles will be at the level of bone section.

e. The periosteum is sharply divided at the level of bone section.

f. The main nerves are gently pulled down, smoothly divided and allowed to retract out of the stump end. Nerves are not ligated, cauterized, injected, or otherwise treated by any fancy technique.

g. The tourniquet should be removed after the main vessels have been ligated and complete hemostasis obtained. The skin flaps are closed by simple interrupted skin sutures. The use of subcutaneous and stay sutures is not

only unnecessary but contraindicated in that they further traumatize already ischemic flaps.

h Drainage should be used more or less routinely for 24 to 48 hours in all amputation stumps because of the tendency for postoperative drainage from the mass of sectioned muscle and from the bone.

3 Postoperative care There is no substitute for complete bed rest, elevation and proper splinting in amputations below the knee until complete wound healing has taken place. A period of at least 3 to 4 weeks is required for proper healing of these cases. Other amputations may heal in less time. Postoperative splinting is preferable to skin traction even in cases in which the skin flaps are tight. Amputations through, or above, the knee should not be elevated as this causes flexion contractures. These patients particularly bilateral above the knee amputees should be turned face down at intervals whenever possible to prevent contractures. The routine use of elastic bandages for compression dressings has been found to be of great value.

Exercises designed to overcome contractures and to strengthen the muscles of the stump are started as soon after wound healing as possible. Wrapping of the stump with elastic bandages for stump shrinkage when properly carried out has proved to be of great value. Exercises and wrapping are the only two forms of physiotherapy which are of value. Massage is always contraindicated as it may be harmful and is of no value.

Occupational therapy has proved to be important both in keeping the patient's mind occupied while he is waiting and also in the training of the use of the arm prosthesis.

4 Extension grafts The extension of the bone length of certain stumps when the normal soft tissues were present but were devoid of a considerable length of bone proved to be a practical and valuable procedure in certain cases particularly in amputations above the elbow. The fibula has been successfully used as an intramedullary extension graft in the medullary canal of the humerus.

The use of extension bone grafts on amputation stumps where any type of skin graft is required to extend the length of the stump is probably not justified in most cases in view of

the disappointing results obtained. This is true of arm stumps as well as various types of amputations of the hand, thumb and fingers.

5 Homogenous bone and bone bank The successful use of freshly transplanted homologous bone grafts in a number of patients with multiple injuries and amputations who had no bone graft donor site led to the limited use of a bone bank at the Thomas M. England General Hospital. The bone was collected from clean reamputations and stored in an ordinary electric refrigerator in glass jars containing normal saline solution saturated with sulfanilamide. The use of bone preserved in this manner was not great enough to warrant conclusions as to its value but the experience was sufficient to suggest further experimentation with the method. This experience did prove beyond doubt that freshly transplanted homologous bone gave good final end results in a high percentage of the cases. These results will be published in a subsequent paper.

6 Sulfu drugs and penicillin The use of medication of this type has undoubtedly been helpful in combating serious infections and has saved time in some cases. The routine preoperative and postoperative use of medication of this type however has not been proved to be of outstanding value.

SITES OF MAJOR AMPUTATIONS

1 Amputation of all digits at or near the metacarpophalangeal joints Phalangization of the metacarpals, with complete removal of the second and third and sometimes the fourth metacarpal bones, and plastic closure of the remaining defect with the formation of a deep cleft was found to be the best solution to this problem type of amputation. The remaining digits thus formed have the advantage of sensation, active motion and prehension. They were so capable of function that all patients operated upon were completely satisfied with the results. The function thus obtained is in some ways similar to that of a Krukenberg stump. This type of stump is very satisfactorily fitted with a cosmetic hand which is used on occasions when active function of the stump is secondary to cosmetic appearance. The technique of this procedure will be described fully in a subsequent article.

Fig Sites of major amputations in upper extremity

2 Amputation at the wrist joint Amputation at the wrist joint has been revived both in this country and in Europe. The carpal bones should be conserved if possible, but if not disarticulation without them is satisfactory. Amputation at this site conserves length and when properly fitted with a prosthesis there is some useful pronation and supination. The prosthesis does not extend above the elbow. Amputation at the wrist is somewhat more difficult to fit with a prosthesis than amputation at the junction of the lower and middle third of the forearm but this can usually be overcome by effort and experience. There have already been many improvements in the prosthesis for amputations at the wrist both here and in England (4).

3 Amputation at the junction of the lower and middle third of the forearm If amputation through the wrist is impossible the next level of choice is at this level or approximately 2 inches above the styloid process. Before the war this was the standard site of amputation in the forearm and was preferred by most surgeons and limb fitters. All possible length should be saved above this level.

4 Short below elbow stumps All length possible should be saved below the elbow since improved methods of fitting have resulted in greater ability to fit these short stumps than ever before. It is possible to fit satisfactorily below the elbow stumps as short as one-half inch in length. The relative stump length may be slightly increased by resection of the biceps

tendon at the time of final operation. This can easily be done by reflecting the anterior flap without the necessity of making a separate incision (3a).

5 Disarticulation of the elbow Amputation at this level was found to be more useful than it had previously been thought to be. It is preferred to amputation at the supracondylar level wherever possible as it gives the stump longer leverage and when properly fitted the patient has better control of the prosthesis, particularly in performing internal and external rotation movements. The prosthesis is fitted with side joints and the type of prosthesis is similar in principle to that used for end bearing thigh stumps.

6 Amputations at the supra-condylar level. This is still the standard site of amputation above the elbow. The supracondylar amputation should be left as long as possible. The site of bone section is immediately above the condyles of the humerus. Above this level all possible stump length should be saved.

7 Short above elbow stumps A stump at least 2 inches in length below the axillary fold is necessary for the active use of a prosthesis. If the stump is shorter all possible bone should be saved including the head and neck of the humerus, despite the fact that amputations at this level will be fitted as disarticulations of the shoulder. Attempts to increase the relative length by section of muscles and tendons have proved disappointing.

8 Disarticulation of the shoulder Disarticulation of the shoulder should never be performed except where surgically necessary. The head and neck of the humerus should be conserved wherever possible for contour and normal appearance. This surgical conservatism also results in better prosthetic fitting and improved prosthetic accomplishment.

SPECIAL METHODS FOR USE IN UPPER EXTREMITY¹

The Krukenberg operation (or stump) The Krukenberg method consists of surgical separation and phalangization of the radius and

¹The basis for the statements used in connection with the Krukenberg and diaphasic methods was personal observation in the American Occupied Zone in Germany. Besides the author was member of the Army Surgeon General's European Commission on Amputations and Artificial Limbs (1946).

ulna so that the resulting claw shaped stump is capable of some prehension and has the advantage of sensation. The use of this procedure is limited to amputations below the elbow of not less than 11 centimeters in length from the lateral epicondyle. Although the method has been widely used in Germany particularly on bilateral amputees with or without eyesight, it probably would not meet with general acceptance in this country. The use of the Krukenberg method however, should be valuable in the surgical treatment and rehabilitation of all blind bilateral amputees.

The cineplastic method The only form of cineplasty still in use is the muscle tunnel type of Sauerbruch. It is still widely used by some surgeons in Germany and the surgical technique has recently been improved considerably. The use of this method has been limited in this country and discontinued in most others chiefly because of inadequate prosthetic facilities. There has recently been considerable renewed interest in cineplasty but extensive use of the method must await further prosthetic research and development which is being carried on by the Committee on Artificial Limbs of the National Research Council. When this work has been completed the method may well be subjected to more extensive trial use when its true value in this country can be finally determined.

LOWER EXTREMITY

1 Amputations through the foot Partial amputations of the foot up to the Chopart level can usually be fitted with shoe corrections and appliances so that they will give very satisfactory function. One of the important lessons learned in the recent War was that the Chopart amputation could not usually be fitted with anything in the way of a shoe correction or a prosthesis which was satisfactory. The Syme amputation is therefore almost always preferable to the Chopart. Much time and worry and dissatisfaction can be prevented on the part of the patient and surgeon by the early and immediate application of the Syme amputation to almost all of these cases. Attempts to improve the function of the Chopart amputation by subastragalar and ankle joint fusion have usually been unsuccessful.

Fig. 2 Sites of major amputations in lower extremity

Center of knee joint is the center of axial motion which is located in the center of the femoral condyle, $\frac{3}{4}$ inch above the joint line.

2 The Syme amputation The Syme amputation when properly performed under the proper circumstances is preferable to any other major amputation in the lower extremity. It is the only amputation recommended at the ankle. The use of amputation at the ankle was greatly revived in this country during the recent war although it had previously been used only to be generally forgotten. Details concerning the Syme amputation during the War have been published in two previous articles (2, 3).

3 Amputations below the knee Although amputations in the lower third of the leg above the Syme level may be satisfactory in some cases they are not generally favored, because of poor circulation. The ideal level of amputation below the knee is generally accepted to be five to seven inches below the knee joint. Most surgeons, who have had the greatest experience, prefer a length of not over 5 to $5\frac{1}{2}$ inches below the knee joint. The use of partial or complete ischial weight bearing has been found to be useful in fitting many imperfect below the knee stumps.

4 Short below the knee stumps The fibula should be completely removed in all below the knee stumps shorter than $3\frac{1}{2}$ inches and these may be fitted as short as $1\frac{1}{2}$ inches below the knee joint if the leg is not too fleshy. Success in fitting these short stumps depends upon the proportion of length to width. Stumps with little soft tissue covering there

fore are more favorable at this level. Some of these short stumps are advantageously fitted with considerable end weight bearing. Section of the hamstring tendons may give additional relative length to the stump in some cases (3a).

5 *The flexed leg stump (bent knee)* Below the knee stumps, which have for any reason definitely proved to be unsatisfactory or are too short for fitting as below knee stumps, may be flexed to 90 degrees and fitted very satisfactorily with a prosthesis with full weight bearing on the bent knee. If sufficient stump length projects posteriorly in this type of fitting it has the advantage of full end bearing without the necessity of any type of belt or suspenders for suspension of the limb. This is one of the oldest methods of prosthetic fitting in the lower extremity the use of which has been revived in the War.

6 *Disarticulation of the knee* Amputations at this site may give excellent results in some cases. It is important that the greatest care be exercised in performing amputations at this level. Unless good healing and full end bearing are obtained the results may be disappointing.

The patella is left in position without removal of the cartilage unless more length is desired in the anterior flap. Removal of the patella in such cases may result in considerable additional relative length of the anterior flap. The cartilage of the femoral condyles is not removed. It is important that the hamstring muscles be sutured to the patella tendon in the intercondylar notch to prevent separation of the skin flaps. When properly fitted with a prosthesis most of these cases need no pelvic or shoulder suspension of the limb since accurate fitting of the socket to the bulbous end of the stump secures it in place.

7 *Supracondylar amputation of the thigh.* The supracondylar tendoplastic amputation apparently gives equally as good results as the Gritti-Stokes. The only difference in these two amputations is that the patella is excised in the supracondylar tendoplastic procedure, whereas it is fixed to the end of the femur in the Gritti Stokes. The supracondylar tendoplastic amputation has the advantage of being

a simpler surgical procedure than the Gritti Stokes. The former was more commonly used in the Army amputation centers than the latter.

8 *Amputations above the knee* In amputations above the supracondylar Gritti-Stokes level the end of the stump should not be longer than 3 inches above the center of the knee joint.¹ Many surgeons of great experience prefer an ideal length of not over ten to twelve inches from the trochanter. If amputations of the thigh are longer than 3 inches above the center of the knee joint, it will be necessary for the prosthetic maker to make the thigh piece longer than the normal thigh, and the shin piece shorter than normal so that the knee joint of the artificial limb can be incorporated. All possible length should be saved above this level.

9 *Short above the knee stumps* It is possible for above the knee stumps as short as 2 inches, measured from the crotch to be fitted as above the knee amputations. Here again this depends somewhat on the proportion of length to width the thinner ones being preferable. If a short thigh stump proves to be too short to be fitted as an above the knee amputation it may be fitted with a tilting table as a hip joint disarticulation when the stump is flexed to 90 degrees. The head, neck, and trochanter should never be removed except when absolutely necessary as the presence of this structure helps to stabilize the prosthesis and it conserves the normal contour of the pelvis.

ADVANCES IN BONE GRAFT SURGERY ATTRIBUTED TO WORLD WAR II

GEORGE K. CARPENTER, M.D. F.A.C.S. Nashville, Tennessee

BONE graft surgery as performed by the military surgeons during the early months of World War II was little different from that performed in civilian life. Sound civilian surgery became good military surgery. The advances derived from war experience should now be applied to present day civilian practice.

Experience has shown that better end results are obtained when both the patient as a whole and his extremity are effectively prepared for bone graft surgery. The patient's general condition should be at its best prior to surgery. Blood transfusions are often indispensable in rendering the patient in optimum condition for surgery. It has been well shown by Brown, Shaw, Mech and others that existing scar tissue must be appropriately treated prior to bone graft surgery. Once nonunion is accepted, the extremity is subjected to a well supervised preoperative program of physical therapy which is outlined to improve circulation and muscle tone and to mobilize the joints.

Chemotherapy plays an important rôle in bone graft surgery. This is particularly true since nonunion so frequently follows a compound fracture. Chemotherapy will not permit bone graft surgery in the presence of infection. It is our practice to delay bone graft surgery until approximately 3 months following complete wound healing. The time interval between complete wound healing and bone grafting may vary somewhat depending upon the character and duration of the infection but it is safer for the patient if the surgeon waits longer than was necessary rather than to operate too early. It is our practice to employ adequate penicillin therapy for 2 days prior to surgery and for approximately 5 days following surgery.

It is believed that nonunion is too often not recognized and accepted in an early stage and as a consequence bone grafting is frequently unnecessarily delayed. So called delayed union usually progresses to nonunion. To treat delayed union for 3 months and at the end of this time find that bone graft surgery is necessary is most time consuming to the patient. Prolonged immobilization is detrimental to restoration of function. The morbidity of a

Fig 1 Case 1: Nonunion of 6 1/2 years duration in an 8 year old child
Fig 2 Case 1: Three and a half months after bone graft with iliac bone

fore, are more favorable at this level. Some of these short stumps are advantageously fitted with considerable end weight bearing. Section of the hamstring tendons may give additional relative length to the stump in some cases (3a).

5 *The flexed leg stump (bent knee)* Below the knee stumps, which have for any reason definitely proved to be unsatisfactory or are too short for fitting as below knee stumps, may be flexed to 90 degrees and fitted very satisfactorily with a prosthesis with full weight bearing on the bent knee. If sufficient stump length projects posteriorly in this type of fitting it has the advantage of full end bearing without the necessity of any type of belt or suspenders for suspension of the limb. This is one of the oldest methods of prosthetic fitting in the lower extremity the use of which has been revived in the War.

6 *Disarticulation of the knee* Amputations at this site may give excellent results in some cases. It is important that the greatest care be exercised in performing amputations at this level. Unless good healing and full end bearing are obtained, the results may be disappointing.

The patella is left in position without removal of the cartilage unless more length is desired in the anterior flap. Removal of the patella in such cases may result in considerable additional relative length of the anterior flap. The cartilage of the femoral condyles is not removed. It is important that the hamstring muscles be sutured to the patella tendon in the intercondylar notch to prevent separation of the skin flaps. When properly fitted with a prosthesis, most of these cases need no pelvic or shoulder suspension of the limb since accurate fitting of the socket to the bulbous end of the stump secures it in place.

7 *Supracondylar amputation of the thigh* The supracondylar tendoplastic amputation apparently gives equally as good results as the Gritti Stokes. The only difference in these two amputations is that the patella is excised in the supracondylar tendoplastic procedure, whereas it is fixed to the end of the femur in the Gritti Stokes. The supracondylar tendoplastic amputation has the advantage of being

a simpler surgical procedure than the Gritti Stokes. The former was more commonly used in the Army amputation centers than the latter.

8 *Amputations above the knee* In amputations above the supracondylar Gritti-Stokes level the end of the stump should not be longer than 3 inches above the center of the knee joint.¹ Many surgeons of great experience prefer an ideal length of not over ten to twelve inches from the trochanter. If amputations of the thigh are longer than 3 inches above the center of the knee joint it will be necessary for the prosthetic maker to make the thigh piece longer than the normal thigh, and the shin piece shorter than normal so that the knee joint of the artificial limb can be incorporated. All possible length should be saved above this level.

9 *Short above the knee stumps* It is possible for above the knee stumps as short as 2 inches, measured from the crotch to be fitted as above the knee amputations. Here again this depends somewhat on the proportion of length to width the thinner ones being preferable. If a short thigh stump proves to be too short to be fitted as an above the knee amputation it may be fitted with a tilting table as a hip joint disarticulation when the stump is flexed to 90 degrees. The head neck and trochanter should never be removed except when absolutely necessary as the presence of this structure helps to stabilize the prosthesis and it conserves the normal contour of the pelvis.

ADVANCES IN BONE GRAFT SURGERY ATTRIBUTED TO WORLD WAR II

GEORGE K. CARPENTER, M.D. F.A.C.S. Nashville, Tennessee

BONE graft surgery as performed by the military surgeons during the early months of World War II was little different from that performed in civilian life. Sound civilian surgery became good military surgery. The advances derived from war experience should now be applied to present day civilian practice.

Experience has shown that better end results are obtained when both the patient as a whole and his extremity are effectively prepared for bone graft surgery. The patient's general condition should be at its best prior to surgery. Blood transfusions are often indispensable in rendering the patient in optimum condition for surgery. It has been well shown by Brown Shaw, Mech and others that existing scar tissue must be appropriately treated prior to bone graft surgery. Once nonunion is accepted, the extremity is subjected to a well supervised preoperative program of physical therapy which is outlined to improve circulation and muscle tone and to mobilize the joints.

Chemotherapy plays an important rôle in bone graft surgery. This is particularly true since nonunion so frequently follows a compound fracture. Chemotherapy will not permit bone graft surgery in the presence of infection. It is our practice to delay bone graft surgery until approximately 3 months following complete wound healing. The time interval between complete wound healing and bone grafting may vary somewhat, depending upon the character and duration of the infection but it is safer for the patient if the surgeon waits longer than was necessary rather than to operate too early. It is our practice to employ adequate penicillin therapy for 2 days prior to surgery and for approximately 5 days following surgery.

It is believed that nonunion is too often not recognized and accepted in an early stage and as a consequence bone grafting is frequently unnecessarily delayed. So called delayed union usually progresses to nonunion. To treat delayed union for 3 months and at the end of this time find that bone graft surgery is necessary is most time-consuming to the patient. Prolonged immobilization is detrimental to restoration of function. The morbidity of a

fracture is in direct proportion to the extent and duration of the disability and its associated economic sequelae.

In cases in which the surgeon is reasonably assured that nonunion is inevitable bone grafting should not be delayed except as is necessary to fulfill the usual prerequisites for bone graft surgery. Unless the surgeon is reasonably assured that so called delayed union will soon progress to solid bone union it is believed that bone grafting should be performed without delay. Carpenter

Rosenfeld and Meek have described the treatment of limited union by reinforcement bone grafts as a procedure planned to shorten the time needed to obtain a bony union of sufficient size and strength to permit early and unprotected function of the extremity. This treatment of limited union decreases the disability and thereby reduces the morbidity of the fracture.

A patient with nonunion requires a careful consideration of the individual problem at hand and a method of procedure is planned which will assure the maximum of function in the minimum of time. Needless to state, the

procedure of choice must be a safe one for the patient, and this will necessitate sound surgical judgment and respectful understanding of morbidity. Cancellous bone such as that obtained from the wing of the ilium offers exceptional qualifications as the graft of choice. It is ideal for a spinal or sacroiliac fusion and in nearly all joint fusions which necessitate the use of autogenous bone. Unfortunately the usual bone graft operation for nonunion is performed with the patient on his back, and since the posterior wing of the ilium presents the better donor site, certain technical difficulties most often make the ilium an impractical site from which to obtain the grafts. Adequate internal fixation of the fracture site is very advantageous and can be better obtained by the application of an onlay graft with screw fixation. Cancellous bone in lesser quantities can, of course, be obtained from the tibia. The tibia serves as the best donor site in the majority of cases. Multiple chip grafts as can be obtained from the tibia, also serve to stimulate osteogenesis.

The long bones may be better grafted by the application of long tibial grafts with cancellous bone and chips packed about the fracture site and along the graft. Two to four screws will as a rule adequately maintain in

ternal fixation of the fracture and graft. Frequently in nonunion of the femur the fracture is fixed by the application of a six screw metallic plate to facilitate postoperative treatment in a Thomas splint and a Pearson attachment traction apparatus. Nonunion of the femur thus treated by the application of a metallic plate in addition to a tibial graft and cancellous bone eliminates the use of plaster and permits early knee motion. Although it is believed that positive fixation of the fracture and of the graft very materially hastens the union, such treatment is not always employed.

FIG 13.

FIG 14.

Fig. 13. Case 7. Seven and a half months after fracture of femur.

FIG 15.

FIG 16.

Fig. 15. Case 8. Two and a half months after fracture of femur.

Fig. 16 and 17. Case 8. Five months after onlay graft and plate.

As a general rule plates and screws are used sparingly if at all in treating a case of nonunion which previously showed infection even though wound healing had been complete for at least 3 months. Bones well covered with muscles, such as the shaft of the humerus and femur will tolerate plates and screws much better than such locations as the lower third of the tibia. The site of the nonunion should be cleared of scar tissue and sclerotic bone, but when extensive infection has been present, it may be unwise to treat the fracture site. An onlay graft may be reasonably expected to take without performing an extensive resection of scar tissue and sclerotic bone. A sliding inlay graft is an excellent procedure for treatment of nonunion of the tibia following a simple fracture but when nonunion follows a compound fracture of the lower third of the shaft of the tibia an onlay graft, without screw fixation is applied to the lateral aspect of the tibia. Intermedullary grafts are rarely if ever used. With loss of substance multiple grafts with much cancellous bone and chips are employed in an effort to restore the bone to its normal size. It is imperative that plenty of bone be used in every case. The surgeon must be ingenious and resourceful and an exponent of sound surgical principles.

SUMMARY

The advances in bone graft surgery emanating from the experiences of World War II which are equally applicable to civilian practice are briefly as follows

1 A full appreciation of the value of rendering the patient in optimum condition for surgery and maintaining his blood and nutritional requirements throughout the convalescence, as so well described by Lyons.

2 Like the patient as a whole, the extremity itself is likewise put in optimum condition for surgery.

3 Chemotherapy will permit the infected compound fracture with nonunion to be grafted earlier but never until the elapse of an adequate time interval following complete wound healing.

4 An early recognition of nonunion will permit grafting as soon as the usual prerequisites for bone graft surgery are satisfied.

5 Adequate internal fixation of the fracture and of the graft preferably by using screws and a tibial graft seems to stimulate the osteogenetic activities of the graft and is desirable except when the site of fracture was previously the seat of an extensive infection.

FRACTURE OF THE CARPAL SCAPHOID

MATHER CLEVELAND M D F.A.C.S New York, New York

THE navicular of the hand is invariably called the scaphoid by those who write of its pathologic state. Oblatz and Halbsteln (1) described the nutrient foramina on which the blood supply of this bone depends. The largest and most numerous of these foramina are distal to the constricted portion called the waist by clinicians. These writers concluded that a complete fracture at the waist would seriously interfere with the blood supply of the proximal fragment in about a third of the cases. *This is the important factor in the healing of these fractures.*

Mechanism These fractures are due to indirect violence transmitted from the outstretched hand along the radial axis of the hand and forearm. These radial axis injuries are in order of sequence but not frequency as follows (1) fracture of the first metacarpal bone, (2) fracture of the greater multangular bone, (3) fracture of the carpal scaphoid, (4) perilunate posterior dislocation of the carpus, (5) Colles fracture, (6) fracture of the head of the radius. These lesions occur separately and in combination (Fig 1 and Fig 2). In the younger age group such as we had to deal with in the armed forces whose strong muscles resist the indirect violence fracture of the carpal scaphoid occurs 4 to 5 times as frequently as Colles fracture. In the more elderly with flabby muscles the wrist immediately extends and Colles fractures predominate.

Clinical recognition of the fracture If after a fall on the outstretched hand or similar trauma, the patient complains of pain at the radial side of the carpus, inability to grasp firmly, and shows no obvious deformity but constant, definite tenderness in the interval between the long and short extensor tendons of the thumb a fracture of the carpal scaphoid should be assumed to exist until its absence is proved by roentgenogram.

Presented in the symposium on Fractures before the Clinical Congress of the American College of Surgeons, Cleveland Ohio December 16-20, 1946.

Roentgenography The use of the roentgenogram as an aid to diagnosis in a very high percentage of wrist injuries led to the discovery of an enormous number of these carpal scaphoid fractures in the armed forces. A complete or widely displaced fracture may be immediately revealed by the first roentgenogram in conventional positions. At times the first roentgenogram will fail to reveal the fracture which will be readily seen 2 weeks later due to absorption at the fracture line. Those views which show this fracture to best advantage are (1) an anteroposterior with the hand in marked ulnar deviation and (2) a postero-anterior in 45 degree angle oblique projection.

The fracture A few of these fractures occur at the tuberosity where the transverse carpal ligament is attached. These avulsion fractures heal uneventfully in short order.

The fracture under consideration occurs at the waist and heals according to the blood supply which remains to the proximal fragment. Fractures with an adequate blood supply to the proximal fragment should heal with 8 to 10 weeks of immobilization while those with an

Injuries recognized and treated immediately. a, at left, Roentgenogram of right wrist showing perilunate dislocation — a complete badly separated fracture of the scaphoid. a, at right, Roentgenogram of left wrist on day of injury showing fractures of greater multangular, carpal scaphoid and Colles. b, at left, Roentgenogram of right wrist July 30, 1946, 8 months after injury. Dislocation reduced, scaphoid fracture ununited. a, at right, Roentgenogram of left wrist July 30, 1946, 8 months after injury. Fracture of greater multangular and Colles are united. Carpal scaphoid ununited. This case is shown as bilateral carpal scaphoid fracture with three other associated radial axis injuries in the two wrists. This soldier refused further treatment, stated that his symptoms were minimal. He could do his civilian job and requested discharge from the service.

inadequate blood supply will require up to 20 weeks or longer before healing ensues. Unfortunately there is no means of determining in advance into which group any given fracture of the scaphoid falls.

TREATMENT

Treatment of the fracture is by prompt immobilization of the wrist in a glove type circular plaster splint extending from just below the elbow to the distal palmar flexion crease, allowing full motion in the fingers. The wrist is in slight dorsal flexion. The thumb is usually immobilized in anatomic position beyond the distal joint. Various positions of the thumb have been advocated with equally good results reported. This does not appear to be a vital factor.

Since no complete fracture of the carpal scaphoid through the waist heals in much less than 8 weeks, plaster immobilization should be continuous for this period. The plaster splint is then bivalved, a roentgenogram is

taken, and the splint immediately reapplied. If the fracture is united the splint is discarded. If union of the fracture is doubtful a new circular plaster splint is promptly applied. If this roentgenogram reveals the proximal fragment with its original density while the distal fragment shows atrophy, there is definite evidence of interference with blood supply to the proximal fragment, and prolonged immobilization of the wrist up to 20 weeks or longer may be indicated.

RESULTS OF TREATMENT

Shands reported that 195 of 198 carpal scaphoid fractures treated by trained orthopedic surgeons in 6 Army Air Force hospitals resulted in union an incidence of 98.5 per cent. Oblatz (2) reported in greater detail a series of 28 carpal scaphoid fractures from an Army Ground Force Hospital. He personally

followed these cases until plaster splints could be discarded. Union occurred in every case without aseptic necrosis in a single instance.

These 2 instances are, of course, optimum results obtained by experts. Experience gained by the medical officers of the armed forces offers to civilian surgery two salient facts about this fracture: (1) it is a common injury; (2) with complete knowledge of the problem and proper treatment based on that knowledge, a high percentage of those fractures will heal.

Beware of a diagnosis of sprain of the wrist joint! (Fig. 3)

MANAGEMENT OF COMPOUND FRACTURES IN THEIR EARLY PHASES

OSCAR P HAMPTON Jr MD F.A.C.S St Louis, Missouri

THE advances during World War II in the management of compound fractures in their early phases came not only in improved techniques of excisional surgery in forward hospitals and in the broad application of specific procedures such as delayed closure of the compounding wounds and surgical incisions or delayed internal fixation of malaligned compound fractures several days later in base hospitals, but of greater importance in a change of concept for the management of these wounds. Moreover the basic principles of the science of surgery itself were irrevocably reaffirmed.

Battle received compound fractures were all compounded from without in and were potentially septic because of the usually present extensive soft part and bone damage, the mud clothing and other foreign material often buried deep in the wound and the prolonged time lag from wounding to surgery. The wounds and incisions of initial surgery of necessity remained unsutured and reduction of the fractures was usually delayed 5 to 10 days until the wounded men had been transferred to base hospitals. The comparable lesions in civilian life, then are injuries many hours or days old

with unreduced fractures and open and possibly grossly septic wounds.

In the early experience, The Orr Trueta regimen of closed plaster subsequent to débridement had in general left much to be desired. Slow wound healing by granulation with heavy scar formation was accepted prolonged wound suppuration with necrosis of living tissue was not infrequent inadequate reduction of fractures anticipating malunion or nonunion was often accepted and the prolonged plaster fixation predisposed to extreme muscle atrophy and fixation of joints. Fear of stirring up and establishing limb or life endangering sepsis including gas gangrene had prevented efforts at delayed wound closure, at delayed open reduction and internal fixation of unreduced fractures, and even at radical secondary débridement to combat sepsis, the therapy of which had included only prolonged drainage through the open wound local and systemic sulfonamide in an effort to control the bacterial flora of the wound and immobilization.

Based upon previous experiences and observations, during the Cassino and Anzio impasse in early 1944 and the later offensive attendant to the Fall of Rome, the closed plaster—open wound—fear of surgery in a septic field concept was discarded in favor of that of repair

Traction is being made on a wire through the tibial tubercle while vertical lift is being made on the distal femoral fragment by means of a second wire through this fragment.

tive surgery of compound fractures. The new regimen included aggressive secondary surgery in the several days old and possibly septic wound with delayed excision of dead tissue if necessary, internal fixation of fractures on precise indications and partial or complete closure of clinically clean compounding wounds with obliteration or dependent drainage of residual dead space. Penicillin therapy systematically was employed as a safe guard against invasive infection of living tissue by the bacterial flora of the open wound. It was used as a means to a better surgical result and not in an attempt to sterilize an open wound. Whole blood replacement therapy was used extensively to permit prolonged anesthesia and surgery as an aid in the prevention of chronic sepsis and presumably as an aid to wound healing.

The concept for the newer regimen may be stated as follows:

'Wound sepsis results from the septic decomposition of dead tissue including blood clot in dead space. If a wound is free of dead tissue and if dead space is obliterated or dependently drained and if living tissue is protected from invasive infection by an effective

antibacterial agent the bacterial flora of an open wound may be disregarded and any reparative procedure may be performed within the range of recognized surgical limitations without fear of sepsis and with the anticipation of good wound healing.'

The experiences and successes achieved in the application of this concept in the management of unreduced compound fractures with open wounds several days after the initial surgery permit the following conclusions. The supporting data, mostly have been published.

1. In the prevention or eradication of wound sepsis, regardless of the time lag since injury or duration of sepsis, the surgical excision of dead and devitalized tissue and the obliteration or dependent drainage of dead space are prime considerations. Devitalized tissue is the forerunner of sepsis and when sepsis intervenes, reparative measures are doomed to failure, delayed or nonunion of the fracture may follow and wound healing will be postponed or prevented. Hence the importance of thorough initial surgery in preparation for reparative surgery several days later.

2. Delayed closure of clinically clean wounds that is wounds free of dead tissue and débris

MANAGEMENT OF COMPOUND FRACTURES IN THEIR EARLY PHASES

OSCAR P HAMPTON Jr MD F.A.C.S. St. Louis, Missouri

THE advances during World War II in the management of compound fractures in their early phases came not only in improved techniques of excisional surgery in forward hospitals and in the broad application of specific procedures such as delayed closure of the compounding wounds and surgical incisions or delayed internal fixation of malaligned compound fractures several days later in base hospitals, but of greater importance, in a change of concept for the management of these wounds. Moreover the basic principles of the science of surgery itself were irrevocably reaffirmed.

Battle received compound fractures were all compounded from without in and were potentially septic because of the usually present extensive soft part and bone damage the mud clothing and other foreign material often hurled deep in the wound and the prolonged time-lag from wounding to surgery. The wounds and incisions of initial surgery of necessity remained unsutured and reduction of the fractures was usually delayed 5 to 10 days until the wounded men had been transferred to base hospitals. The comparable lesions in civilian life then are injuries many hours or days old

with unreduced fractures and open and possibly grossly septic wounds.

In the early experience The Orr Trueta regimen of closed plaster subsequent to débridement had in general left much to be desired. Slow wound healing by granulation with heavy scar formation was accepted prolonged wound suppuration with necrosis of living tissue was not infrequent inadequate reduction of fractures anticipating malunion or nonunion was often accepted and the prolonged plaster fixation predisposed to extreme muscle atrophy and fixation of joints. judicious application of these principles that is, the excision of dead tissue when and wherever it is found obliteration or dependent drainage of dead space staged closure of wounds, atraumatic technique with fine hemostats and fine ligatures pressure dressings adequate reduction and immobilization of fractures, and precise splinting and with the

adjuvant use of penicillin and whole blood the objectives of the regimen were achieved Surely the same regimen under the same principles is applicable to many compound fractures of civilian life which are seen many hours days or weeks after injury has occurred and particularly to those with established sepsis

OSTEOMYELITIS FOLLOWING COMPOUND FRACTURES

GROVER C PENBERTHY MD FACS Detroit Michigan

THE changes which have been brought about in civilian practice with respect to osteomyelitis complicating compound fractures have resulted from the application of sound surgical principles and careful attention to detail. Many believe that the advances made in the treatment of these cases are the result of sulfonamides and penicillin. This is not wholly true for while the antibiotics have played an important part good surgical care has been of paramount importance. Antibiotics are best applied systematically and there can be no doubt that a patient in poor general condition does not respond as well to these agents in combating infection as one in a good state of health. In patients who have had acute blood loss or with hemoglobin values low because of long continued infection, it is necessary to give adequate blood transfusions if antibiotics are to be of value.

A debilitated patient is a good host for bacteria. A healthy one resists invasion by organisms. Compound fractures are severe open wounds. The fundamental principles underlying open wounds apply whether the bone is involved or not. The realization and adoption of these principles have resulted from experiences in World War II. Wounds seen early carefully cleansed of as many contaminating organisms and foreign bodies as is possible and

the devitalized tissue carefully debrided are best closed primarily. If this seems not feasible secondary closure (1) of the wound after several days is advisable. If large defects in the skin or soft tissue result immediate skin grafts assist the wound to heal kindly even though they may need replacing later with a full thickness sliding or pedicle graft. Obviously good principles of fracture and wound care must include immobilization. This can and should when possible, be accomplished without the use of screws or plates. Large dead spaces must be obliterated (3) and when this is not possible dependent drainage must be afforded to minimize the complication of osteomyelitis.

Chronic osteomyelitis resulting from compound fracture actually is less frequent today than it was before the war because these principles mentioned above have been more widely recognized as a result of the experiences of World War II. The best treatment for this condition is prevention and careful attention to principles of care of wounds. This is the best prophylaxis we have.

Chronic osteomyelitis should not be confused with hematogenous osteomyelitis which presents an entirely different problem. The two conditions are separate entities and have different clinical pathological radiological and surgical considerations. Unlike hematogenous osteomyelitis this type practically never metastasizes but remains an infection within the bone locally. The treatment of es

Fig. 3 a, Anteroposterior and lateral view of a comminuted fracture of the femur which is the site of gas abscess. The patient had been wounded by a high explosive shell fragment 10 days previously and had received inadequate excisional surgery. Local and systemic sepsis had followed. Although the gas abscess is visible on the roentgenogram, there were no clinical signs of gas gangrene. b, The gas abscess was drained and devitalized tissue was excised through a long posterolateral incision. The dead space about the fracture site was obliterated by fixing the fragments in apposition by means of a six hole bone plate. This illustration shows the fracture partially united 3

months after drainage of the abscess and concurrent plating of the fracture. The wound had been healed since about 3 weeks after the internal fixation of the fracture. c, The wound remained healed and the fracture firmly united in anatomical alignment. Because of some absorption about screw as visualized on roentgenograms, the plate and screws were prophylactically removed with immediate closure of the wound and primary healing. d This illustration reveals the completely healed wound of the thigh (with some excessive scar formation which required later excision and subsequent repair. This end result is a triumph for the principles of reparative surgery.

and of signs of invasive infection is surgically sound provided dead space is obliterated or dependently drained and excessive tension is avoided. The sliding or advancement of flaps to permit closure without tension is often worthwhile. Therefore given a clinically clean compounding wound several days after excisional surgery wound healing by granulation should be scorned and if surgical limitations do not preclude, wound closure by suture or skin graft should be performed. Wound healing while affected by several factors, is a natural cellular growth provided the wound does not contain dead tissue dead space strangulating ligatures, etc. Wound closure may be practiced to the extent to which these qualifying factors can be surgically obviated.

3 The best evidence of adequate excisional surgery is a clinically clean wound 5 days later the optimum time for delayed wound closure. Within this period excellent drainage of wound exudate and residual debris is provided, and closure of wounds before the formation of heavy granulation tissue and reduction of fractures before the fixation of fragment ends are permitted.

4 Despite an unhealed wound inadequate reduction of fractures need not be accepted if it is preventable by open reduction with or without internal fixation. Reduction of the fracture eliminates the dead space about malaligned fragment ends, avoids subsequent manipulations which may produce additional devitalized tissue and anticipates minimum deformity. Internal fixation is detrimental to wound healing only as devitalized tissue is created in its application or as it interferes with soft part coverage of denuded bone.

5 The regimen as a whole may be expected to achieve minimum sepsis rapid healing of wounds with minimum scar maximum reduction of fractures, and maximum functional restoration of the extremity. In this experience no loss of limb or life attributable to the aggressive surgery was reported.

In summary reparative surgery of compound fractures represented a major advance in World War II. Under its principles, the spotlight was moved from the bacterial flora to the pathology of the open wound and a surgical approach was established for the management of septic compound fractures. By

APPLIED ANATOMY IN EYE SURGERY

MEYER WIENER, M.D. F.A.C.S. Coronado California

APPPLIED anatomy serves a twofold purpose. It gives a precise basis to those occurrences and procedures that especially involve anatomical knowledge, and, in addition, it converts an otherwise unusually dull subject into one of interest by associating it with something manifestly useful and practical.

The student of anatomy has a somewhat hazy fanciful notion that his study of anatomical structure will, in some way and at some future time prove useful to him. By incorporating with it its surgical application he is made aware of its value in very much the same way as a series of experiments in laboratory physics relates to sheer theoretical, scientific data.

While it is assumed that eye surgeons, in general, are acquainted with most of the premises which I am presenting it is with the hope that the memory of the dissecting days which have been growing a bit gray with some of us will wish to recall some of the anatomical matters which have the most direct bearing on surgical practice.

In surgery of the lids we must constantly bear in mind the delicate nature of the skin as well as the changes which come with advancing years which have a direct connection with surgical performance. The skin of the eyelid is the most delicate in the body pale and loosely attached. The foreskin approaches it most nearly in texture. However, it is not wise to use foreskin for lid replacement because, for some unknown reason, it nearly always becomes deeply pigmented. If not much is needed, the skin of the opposite lid is ideal if available. Probably next in order is that just back of the ear or that from the inside of the arm.

In old age the skin atrophies and loses its elasticity due to atrophy of the elastic fibers. This sometimes induces spastic entropion since the overaction of the orbicularis has no

resilient skin to overcome it. The Ziegler cautery is effective by causing the skin corresponding to the lower margin of the tarsus to adhere to this border so that it will not curl up and roll over the lid margin. In like manner, cauterization of the conjunctival side in hypertrophic ectropion probably causes the conjunctiva to attach itself to the inner border of the tarsal plate. Sometimes in advanced age there will be considerable tearing with a patent drainage canal, often due to lax skin plus a hypertrophy of the conjunctiva. Making only a few punctures immediately inside the canaliculus will bring in the lid margin just enough so that the lower punctum will contact the globe and again siphon off the tears.

It is well to contemplate the width of the tarsal plate in selecting the type of operation for correction of contractile entropion. The tarsus of the lower lid is much narrower than that of the upper the width of the normal upper being about 10 millimeters and that of the lower about 5 millimeters. Hence in surgical correction of the upper lid, where the tarsus is still wide we may attach the cut edge of the skin near the lid margin to the top of the cleaned tarsus and have a right to expect a satisfactory result. This may be further improved by removing the thickened orbicularis attached to the tarsal plate, producing a wider palpebral fissure. The lower tarsal plate is seldom wide enough to justify utilizing this method so the modified Green Ewing method is recommended, as this does not require a wide tarsus.

The eyebrow is thick and curved so as to protect the eye from sweat and blows. It also helps shade the eye from excessive light by bending over. It should not be plucked and if destroyed by injury should be restored for this and cosmetic reasons. The lashes serve the same purpose and need not be trimmed before surgery. It is often a great advantage to grasp the lashes after operation to pull the lid away from the eye in closing it. The lashes can be replaced by a narrow graft from the

established osteomyelitis following a compound fracture is a problem in the care of the local area supported by systemic treatment to aid in combating the infection and supporting the patient constitutionally. Open drainage with removal of infected areas by saucerization permits drainage after the infection has become localized. This is a principle similar to the treatment of localized infection of other parts. A lesson which has been learned from World War II is that large open defects must not be allowed to remain to depress the vitality of the patient. Skin grafts should be applied as soon as clean granulations have covered the drained area to minimize loss of fluid and discomfort to the patient. These should be applied early even though they are not sufficient in themselves to give good permanent coverage to the area. When such wounds have been properly covered the patient is more comfortable and early reconstructive surgery can be accomplished with the aid of antibiotics.

Prior to World War II it was considered poor surgical judgment to attempt reconstructive surgery in the area where infection had taken place because of the possibility of reactivating the infection. On one of the large orthopedic services (2) of a general hospital in the Zone of the Interior 90 per cent of the procedures were done through the original incisions with approximately 5 per cent flare up of infections. Bone grafting to fill defects was also performed 6 to 8 weeks after wound healing. This has been made possible by general supportive measures and the use of sulfonamides and penicillin systemically. The value of appropriate chemotherapy before and after operation in the care of osteomyelitis cannot be stressed too strongly and prolonged administration is of definite value (5).

Reconstructive surgery of the skeletal system should not be done in the presence of draining sinuses, open draining wounds, or any clinical evidence of wound infection. This concept is no different than it was before the

war. Penicillin or sulfonamides cannot be expected to be of value in the presence of undrained abscesses, the presence of sequestra, detached fragments of bone with aseptic necrosis or any other foreign body.

Frequently large open wounds with considerable loss of skin muscles, tendons, nerves, or blood vessels with bone trauma may be diagnosed as osteomyelitis incorrectly because of the constant drainage or "weeping" from granulation tissue (4). In such cases the drainage will usually stop when the wound is closed by a skin graft if osteomyelitis is not present.

The differences in the care of compound fractures in World War II as compared with World War I are striking. In compound gunshot wounds during the first year of World War I the total mortality was reported to be about 60 per cent (6). With emergency splinting on the battlefield the mortality was reported to be about 12 per cent at the end of the third year. During and following World War I compound fracture wounds were debrided and packed open with vaseline gauze with immobilization by plaster. This continued as the accepted form of treatment even during the late Spanish Civil War (7).

The present concept in the treatment of compound fractures which has resulted from World War II has decreased the morbidity and the incidence of chronic osteomyelitis. The application of the principles usually accepted for other infected wounds, as well as the use of chemotherapy has improved the results in cases of chronic osteomyelitis.

APPLIED ANATOMY IN EYE SURGERY

MEYER WIENER, M D F.A.C.S. Coronado California

APPPLIED anatomy serves a twofold purpose. It gives a precise basis to those occurrences and procedures that especially involve anatomical knowledge, and, in addition, it converts an otherwise unusually dull subject into one of interest by associating it with something manifestly useful and practical.

The student of anatomy has a somewhat bazy fanciful notion that his study of anatomical structure will, in some way and at some future time prove useful to him. By incorporating with it its surgical application he is made aware of its value in very much the same way as a series of experiments in laboratory physics relates to sheer theoretical, scientific data.

While it is assumed that eye surgeons, in general are acquainted with most of the premises which I am presenting it is with the hope that the memory of the dissecting days which have been growing a bit gray with some of us will wish to recall some of the anatomical matters which have the most direct bearing on surgical practice.

In surgery of the lids we must constantly bear in mind the delicate nature of the skin as well as the changes which come with advancing years which have a direct connection with surgical performance. The skin of the eyelid is the most delicate in the body pale and loosely attached. The foreskin approaches it most nearly in texture. However, it is not wise to use foreskin for lid replacement because, for some unknown reason, it nearly always becomes deeply pigmented. If not much is needed, the skin of the opposite lid is ideal if available. Probably next in order is that just back of the ear, or that from the inside of the arm.

In old age the skin atrophies and loses its elasticity due to atrophy of the elastic fibers. This sometimes induces spastic entropion since the overaction of the orbicularis has no

resilient skin to overcome it. The Ziegler cautery is effective by causing the skin corresponding to the lower margin of the tarsus to adhere to this border so that it will not curl up and roll over the lid margin. In like manner, cauterization of the conjunctival side in hypertrophic ectropion probably causes the conjunctiva to attach itself to the inner border of the tarsal plate. Sometimes in advanced age there will be considerable tearing with a patent drainage canal, often due to lax skin plus a hypertrophy of the conjunctiva. Making only a few punctures immediately inside the canaliculus will bring in the lid margin just enough so that the lower punctum will contact the globe and again siphon off the tears.

It is well to contemplate the width of the tarsal plate in selecting the type of operation for correction of contractile entropion. The tarsus of the lower lid is much narrower than that of the upper, the width of the normal upper being about 10 millimeters and that of the lower about 5 millimeters. Hence in surgical correction of the upper lid, where the tarsus is still wide, we may attach the cut edge of the skin near the lid margin to the top of the cleaned tarsus and have a right to expect a satisfactory result. This may be further improved by removing the thickened orbicularis attached to the tarsal plate, producing a wider palpebral fissure. The lower tarsal plate is seldom wide enough to justify utilizing this method so the modified Green Ewing method is recommended, as this does not require a wide tarsus.

The eyebrow is thick and curved so as to protect the eye from sweat and blows. It also helps shade the eye from excessive light by bending over. It should not be plucked and if destroyed by injury should be restored for thus and cosmetic reasons. The lashes serve the same purpose and need not be trimmed before surgery. It is often a great advantage to grasp the lashes after operation to pull the lid away from the eye in closing it. The lashes can be replaced by a narrow graft from the

brow or from the hair line back of the ear. Recently Goldzieher reported some preliminary experiments he made on the skin of three elderly women after some previous experiments on dogs. He applied two estrogenic substances, estradiol and stilbestrol daily to the inner areas of the arms and thighs for a period of 6 weeks. Small sections of the skin taken from these areas showed restoration of the width of the epidermis, the number of cell layers increased, the individual cells larger and the elastic fibers more numerous.

I have seen the skin of the upper lid so lax that it drooped down and cut off some of the temporal field. For this reason as well as for appearance sake, a strip of it was removed.

The levator palpebrae is inserted in the skin of the upper lid the lower third of the tarsus and along with Mueller's muscle to the upper edge of the tarsus. It is mainly these latter fibers with the attached aponeurosis that we use in Cannas' operation, where the paralyzed levator is attached to the tendon of the superior rectus.

The lymph channels from the upper lid pass through the preauricular node; those of the lower lid, the submaxillary node (Trevs). This is important in differentiating the lead of drainage in infections and sometimes helps in locating orbital infections where the septum orbitale has been penetrated.

Paralysis of the sixth nerve is particularly associated with fractures of the base of the skull, owing to its long course beneath the dura and its close confinement beneath the petrosphenoidal ligament. In fact, it was Pannas who first recognized that a fracture of the base of the skull might be manifested by a paralysis of the sixth nerve alone. Crepitus of the lids usually denotes fracture of the nasal bone, although fracture of any of the bones forming the nasal sinus cavities connected with the orbit may give rise to air in the orbit or lids.

The orbital cavity is about half an inch wider in the horizontal than in the vertical direction. Therefore it will be seen that there would be more space between the eye and the orbital wall on the sides than above or below and the greatest interval between the globe and the orbital wall is on the temporal side.

For this reason, growths which start on or at the apex of the orbit, or even on the opposite side may soon find their way to the temporal side of the orbit. Dermoid cysts of the orbit are almost invariably found on the outer side, and although they may appear small, on operation will be found to extend to and be attached very close to the apex of the orbit. It is possible that the orbital septum keeps them within bounds and from protruding forward to any extent.

An intraorbital growth which is not within the intramuscular cone and presents on the temporal side can be reached better through a conjunctival incision than by one through the skin. Sometimes, even with the assistance of x rays, it is not possible to tell whether the growth is beneath or above the periorbita and exploration only will determine that fact. If the bone of the periorbita is involved then access through a skin incision is best. To reach growths in the intramuscular cone a Kroenlein approach seems best. In performing this operation, guard against severing the external rectus too far back or a paralysis may result. If the tendon is cut instead of the muscle belly it can be sewed together without fear of this happening. In performing evisceration of the orbital contents, it is done easily and quickly by separating the periorbita from its attachment to the wall of the orbit and then continuing to loosen it with a periosteal elevator back to the apex then cutting off the entire mass from its apical attachment. A clean orbital wall is thus secured and with a minimal amount of bleeding. The cavity must be kept packed sufficiently tight to keep the lids on a stretch, which will otherwise shrivel and atrophy. Of course, if one does not expect to preserve the lids and eventually fill up the orbital cavity then the lid margins may be freshened, sewed together and utilized to serve as a covering for the denuded orbital wall.

The conjunctiva is very loosely attached to the globe in man. The reverse of this is noted in operating on animals' eyes even in monkeys. Man having a smaller cornea in proportion to the size of the globe than any other animal, necessarily has more of his sclera covered with conjunctiva, exposed than any other creature. The negro, having a larger eye than

the caucasian, makes this still more noticeable. This makes it easier to perform surgery on man than on animals, as anyone who has experimented on animals' eyes will have observed. There are other reasons also. This looseness of the conjunctiva is of value in eye surgery in several ways, such as making conjunctival flaps to cover the cornea correcting mild cases of symblepharon and in other plastic procedures. The distance of the conjunctival fornix from the upper lid margin is from 20 millimeters to 25 millimeters. The tarsal plate is from 10 millimeters to 12 millimeters wide. The distance of the fornix to the corneal margin is 8 millimeters to 10 millimeters. Hence, we have a loose surface of conjunctiva 18 millimeters to 22 millimeters wide from which we may easily take half or three quarters for use of a conjunctival transplant on the other eye socket, or for use in restoring the lining of the canaliculus in a plastic operation for restoring its lumen.

Pterygium is described as a conjunctival growth extending over the cornea. At any rate, the underlying cornea is always involved with destruction of Bowman's membrane not only immediately beneath the pterygium but according to Fuchs, to a point about 3 millimeters beyond the apparent apex. In my experience recurrences can be almost invariably prevented if one includes this involved corneal area in his dissection and resects a few layers of the cornea proper beneath the destroyed Bowman's in dissecting off the pterygium.

The most common tumor of the conjunctiva is the naevus. Many are not pigmented and few of them are malignant. About 10 per cent of the tumors are dermoids and in their removal one must bear in mind that the underlying sclera may be very thin.

While ballooning out the retrotarsal fold with 2 per cent procaine to which a drop or two of epinephrine has been added will completely anesthetize both surfaces of the lids for practically all operations on the lids proper so that no pain will be experienced when the tear drainage apparatus is involved, more than that is required. For the lids all of the terminal nerve endings are thus caught supplying the entire thickness of the lids. In order to anesthetize the canaliculus and sac so

that no pain will be felt by the patient to catch all of the nerves supplying the canaliculus one must first instill a drop of pontocaine then insert a small wad of cotton soaked with pontocaine and epinephrine in the inner canthus and after waiting about a minute insert a fine hypodermic needle into the conjunctiva just behind the punctum and slightly temporarily to it, inject a drop or two of the solution of 2 per cent procaine the needle is then advanced in the loose tissue along the course of the canaliculus and drop by drop injected additionally as it is pushed toward the sac. When it reaches the periosteum covering the sac wall a sharp momentary pain is felt until a drop is injected here. Here, the periosteum is very sensitive as the main branches of the supratrochlear and infratrochlear nerves are encountered. One may now pass the dilator and probe into the canaliculus and down through the sac without the patient experiencing any pain. This, together with the anesthetization of the nasal mucosa by the otolaryngologist is sufficient for the intranasal dacryocystorhinostomy.

In doing an extranasal operation or in removal of the sac, one must block the supratrochlear and infratrochlear and the infraorbital. In passing a probe down the nasal duct one is much more apt to make a false passage with a small probe than with a large one. The lumen of the sac is not just a smooth tube, but is often sacculated in such a manner that the small probe will pass into one of these pockets and penetrate the lining whereas a larger one might spread the lumen so as to obliterate the defect temporarily and go right on through. Pictures of these anatomical variations illustrated in both Whitnall and Schaeffer should impress this fact on our minds with impelling force.

One of the most frequent sources of failure in performing any type of intranasal tear sac operation is the failure of the surgeon to make his opening through the bone and sac inside the nose low enough so that the fluid will drain into the nose and not leave a pocket below the opening holding pus. Another of course, is failure to keep the opening patent. It is essential that the puncta be in contact with the globe and that the canalicula not be slit, in

order to have complete drainage. The canaliculi are also shortened by blinking making them wider and thus helping to carry off the tears. In old age when laxity of the skin sometimes causes the puncta to drop away from the globe, relief can be had by a limited Ziegler cauterization.

In operations on the cornea it is well to recall that normally it is thinnest at the center where it averages about 0.8 millimeter widening at the periphery to about 1.2 millimeters. It gets thinner with advancing years and may be less than 0.5 millimeter at the center in the aged. This, plus the loss of resiliency accounts for the sinking in or collapse of the cornea in very old people after cataract incision. A bubble of air injected into the chamber will maintain the normal curvature of the cornea until it has healed.

While Bowman's membrane, if destroyed never regenerates, it is not an essential part of the cornea for either visual or protective purposes. One may resect a corneal scar and obtain clear vision in its absence with apparently no more hazard to infection in its absence than if it were present. In resecting the cornea for corneal scar or peeling it off it is well to bear in mind several things. First, the formation of connective tissue producing the scar creates a much thicker protective shell than the normal cornea. This means that the cut, in preparation for peeling, must be deeper than one would make in a normal cornea, in order to get below the scar formation. Most eye surgeons fall in their corneal resections by not keeping this fact in mind. It also requires more pressure with the knife. It is also less flexible than the normal cornea and cannot be pulled back too much without endangering perforation of the thin underlying transparent cornea. Second in making the crucial incision with the scalpel don't forget that you are not cutting on a flat surface, but over a convexity with a radius of about 80 millimeters. Hence, the handle of the knife must be raised in starting the incision at the limbus and gradually lowered as the cut proceeds toward the opposite margin so as to keep the cutting edge, and not the point of the knife, in contact with and conforming with the corneal curve. This enables one to make his primary

cut much deeper without the danger of perforation. Third, and no less important an anatomical point to bear in mind is that the lamellae, normally about 60 in number and from 1.3 microns to 2.5 microns thick, run the entire width of the cornea, crisscrossing with each other at right angles and with very little interlacing so that they run almost parallel to the curved surface. When one picks up a single section to be peeled off it is essential that he stay in the same layer as that in which he started otherwise whenever he cuts across the intervening layers, connective tissue will form with resulting scar. By following proper technique, closely watching the line of cleavage, this is not difficult to do.

In an article by Edward Jackson on "The Function and Structure of the Eye," he stressed the fact that transparency depends on permeability to some substances of the transparent membranes, which included Bowman's and Descemet's in the cornea, capsule of the lens, Bruch's membrane of the choroid, and their impermeability to others. Rupture brings about loss of transparency. The cornea may lose its transparency from transudate or edema, as in glaucoma exudate, as in keratitis blood staining from blood in anterior chamber becoming hemolyzed scar tissue formation and dissolving of the cement substances between the lamellae in the stroma so that the refraction index is interfered with. This latter is probably due to infiltration of aqueous, such as that due to rupture of Descemet's from birth injury. Edema due to entrance of fluid through the epithelium can be differentiated and temporarily cleared by the glycerine test suggested by Cogan. Jackson lays continuous stress on the resilience of the cornea and refers to Salzmann's description of the arrangement of the layers, because it is more important and easier to understand when considered as a provision for resilience. Hence, no compression bandage after a corneal cut or cataract operation and keeping the wound elevated. He quotes Ellett, speaking of sutures in cataract operation "I think it does give a relative assurance against prolapse, but then there is still enough trouble from this source to lead me, after a rather extensive trial of the simple operation to give up

in favor of the combined operation, except in such cases where the cosmetic effect was a thing to be considered.' Jackson used no corneal stitch relying upon the resiliency of the cornea.

The elasticity of the cornea is greater in the vertical than in the horizontal direction which may account for the astigmatism in glaucoma according to Schreder who found it to be anisotropic that is exhibits different properties when tested in different directions.

The cornea is about 12 millimeters in diameter, but the sclera extends 1 millimeter over the edge in the horizontal and 2 millimeters in the vertical meridian. In some cases it extends 3 millimeters or even 4 millimeters over the edge in the vertical meridian especially so in glaucoma cases. This is a fortunate arrangement in shelving the cornea. This broad limbus is marked in *hydropthalmus* too.

The epithelium around the limbus is potentially a pigment bearing tissue this can especially be noted in animals one may therefore get a pigmented papilloma at the limbus with out its being a melanoma.

The sclerocorneal junction is the weakest part of the eyeball. Rupture of the globe at this point may find the lens under the conjunctiva. If the lamina papyracea, which forms the inner wall of the orbit, should rupture then the eyeball will not rupture. One or the other may rupture, but never both. Decemet's membrane may rupture in birth injuries or in keratoconus and lead to permanent clouding of the cornea, probably through absorption of the interlining cement substance of the layers. Decemet's membrane is easily detached, as happens in doing a trephine or cyclodialysis. It curls under certain conditions and is very elastic. Unlike Bowman's it rapidly regenerates. It is really a crust formation laid down by the endothelium lining the inside of the cornea. This is contrary to the opinion of Elliott, who stated that it and the endothelial lining never regenerated and recommended denuding the endothelium just beyond the limits of the trephine opening so that the opening would not fill up.

At the periphery of Decemet's membrane in most people lies the anterior marginal ring as a circular band. It may go only part way

around and be rudimentary and can be seen with the gonioscope. Decemet's membrane is more resistant, both to the trephine and to infection than is the stroma. One may find 'warts (cornea guttata) around the periphery of Decemet's, which can be seen with the slit lamp and sometimes with the gonioscope. So long as they remain in the periphery they are of no special significance but if located in the center of the cornea the vision may be reduced as much as down to 20/40 or 20/70, and this must be kept in mind in cases of otherwise unexplainable reduced vision. They sometimes permit the aqueous to leak into the cornea.

There are a number of things which make knowledge of the scleral structure a matter for serious consideration in eye surgery. The sclera is about 0.6 millimeter thick at the limbus. Just back of the insertion of the muscles it is thinnest—0.3 millimeter or less. This is where the sutures for recession are placed, and fortunately need not, and should not be deep. Going back to the equator it thickens to 0.6 millimeter and increases to 1.0 millimeter in the back. At the point of entrance of the optic nerve it is very thin owing to the perforations of the lamina cribrosa. On account of this inequality of the thickness one can easily see the futility of using pins in operating for retinal detachment for, if the pins are set for the proper depth in the thin area, they will not be deep enough where the sclera is thickest. The reverse is also true. The zone overlying the ciliary body is a circular area concentric to the limbus 5 to 6 millimeters back. The equator is 13 to 14 millimeters back of the limbus. The area of the venae vorticosae is represented by a concentric band 3 millimeters wide and 18 to 21 millimeters back of the limbus, or 5 to 8 millimeters back of the equator. The superior temporal vena vorticososa lies 7 millimeters back of the equator, the superior nasal 7 to 8 millimeters the inferior temporal 5 millimeters and the inferior nasal 6 millimeters. These exits can be seen and in operations for detached retina and posterior sclerotomy these positions must be kept in mind. In posterior sclerotomy it is best to keep near the equator to avoid these and the long ciliary vessels.

Calcification of the sclera is very common in old age and follows absorption of the elastic

fibers in the sclera. This tends to give one the impression of increased intraocular tension by the finger test which is not borne out with the tonometric measurements. Again the point of the cataract knife may encounter one of these hard particles and interfere with making a satisfactory section. They are usually found on the nasal side as grayish depressions, about 4 millimeters back but exceptionally may appear further forward near the margin. If this process is far advanced the eye loses its power to adjust itself to lessened volume, as when the chamber is opened and the lens removed this can be made up by injecting air into the chamber. This factor may account for choroidal detachment, according to Fuchs.

The emissary perforations in the sclera lie 4 to 6 millimeters back of the limbus and are of great importance. Sometimes the long ciliary nerves loop up and look like small, gray tumors in this region. These have been excised under this delusion which is followed by anesthesia of the corresponding width of the cornea. They can be easily differentiated after having first anesthetized the eye by grasping the mass which induces severe pain. Old glaucoma can often be suspected by the enlargement of the ciliary arteries emerging suddenly from these openings, giving the impression of being more greatly enlarged than they really are. New growths of the ciliary body often emerge from the emissaries and give the impression that they are autonomous, localized ones. Transillumination and other means will determine such.

The sclera is loosely attached to the choroid except where the vessels and nerves penetrate it. In making an incision for cyclodialysis, a sharp corneal hook picks up the sclera, making it very easy to cut through the sclera without touching the choroid, since traction with the hook pulls the sclera away from the choroid. Be sure to make the cut in a place free from vessels which is not hard.

In performing posterior sclerotomy for glaucoma, it is essential to use a knife just as sharp as one would wish for in making a cataract incision and thrust it quickly through into the vitreous with the blade parallel to the antero-posterior fibers so as not to separate the retina from the choroid. As the blade is withdrawn

the incision is enlarged toward the posterior pole. There is a definite place for this little used operation one of which is in cases in which after a drainage operation the iris or ciliary body has come forward into the wound following an apparently successful operation, causing the tension to rise again. The release of the pressure behind the lens will often cause the ciliary hernia to recede and remain back. There need be little or no bleeding if the technique is carried out properly. This admonition must also be heeded in making the incision for the removal of foreign bodies by the posterior route. In this case the incision must be fully 50 per cent larger than the largest diameter of the foreign body for one never knows which end is coming first and it may even come broadside. A long incision heals just as quickly as a small one and does not invite danger of retinal detachment, in my experience, even though one fails to perform electrocoagulation as a preventative measure.

The capsule of Tenon is both membranous and elastic. It is more or less adherent at the attachment of the muscle tendons and in some places to the fat of the orbit. Semeraro found that in tests carried out on the cadaver Tenon's capsule is nonexistent in some cases. This fact may account for the slipping out of the capsule of the implant in many cases of enucleation where the operation seemed to have been well carried out. We have never encountered this condition in the living eye in the many operations involving the muscles, although it does seem to be much less developed in some cases than in others. There is no actual space between the ocular surface of the capsule and the orbital surface opposing it, but the two are connected by a felting of very fine strands of connective tissue. These are loose enough to permit the eyeball to move freely in a limited way but in extreme excursions both globe and capsule move together as a whole in a bed of orbital fat, which is loosely connected to the capsule behind. There is a difference of opinion as to how far forward the capsule extends. Sobotta states that it terminates at the upper retrotarsal fold and at the insertion of the muscles. Most authorities agree that it blends with the conjunctiva as far forward as the corneal margin.

Where the vessel sheaths blend with the capsule, they give offshoots to the orbital walls known as the check ligaments. We shall speak of these in a moment. The septum orbitale is a thin membrane of connective tissue which extends from the entire orbital margin toward the palpebral opening and tends to hold infections to either the orbit or to the anterior part of the globe. The capsule of Tenon as well as the periorbita and the sheath of the optic nerve, are continuous with the dura. For this reason it is dangerous to perform enucleation in panophthalmitis with marked cellulitis of the orbit, as it may lead to meningitis and subsequent death of the patient. I saw this happen once while I was a medical student. Evisceration is here indicated. In removing the contents of the globe it is imperative that no remnant of the uveal tract remain. The choroid is firmly attached in two places posteriorly, where the posterior ciliary vessels and nerves enter and in front where the anterior vessels and nerves pass through the emissaries. These points must be most carefully inspected on conclusion of the operation. When all of the pigmented material has been removed, the sclera will be seen as a white smooth surface and there will be no bleeding. If the usual enucleation is done and a glass ball is inserted it is well to figure out just how large the cavity is so that too large a one will not be introduced and be expelled. If we could count on preserving every bit of capsule as far forward as the attachment of the muscle tendons and not allow any for the depth of the sutures, then we might easily put in a 14 millimeter or even a 15 millimeter implant in the capsule. However, anteriorly the capsule is so intimately connected with the sclera that it isn't detached for several millimeters back of the insertion. Therefore, if one inserts a small ball, not over 12 millimeters in diameter there will be less stretching of the capsule in sewing it in and more likelihood of it not being expelled. This rule holds good, also for implanting after evisceration for the reason that taking off all of the cornea and part of the sclera lessens the diameter of what remains. It would seem that Burch's recommendation of leaving the cornea intact and implanting a larger sphere should give a far better result.

In a clean enucleation it is not necessary to sew the tendons together for they are closely attached to the capsule and fall naturally together whether the capsule be sewed or not. In enucleating a globe for absolute glaucoma where we have a very deep cup, if the nerve is cut too closely one is apt to lose vitreous for there is no vitreous hyaloid membrane either over the nerve head or the ora serrata. Women's eyes are larger than men's and the negro eye is larger than that of the white man hence, a slightly larger implant can be used.

In man, the conjunctiva is very loosely attached to the globe except at the limbus. It stretches readily. The capsule of Tenon is supposed to run forward beyond the attachment of the muscle tendons to blend with the conjunctiva. For all practical purposes one can almost forget it is there, unless it constitutes the deep layer under the loose, conjunctival connective tissue which bugs the sclera. In making a flap for sclerocorneal trephine, one must hug the scleral surface closely with the blunt scissors in order to obtain a thick, protective flap. At the point where the sclera and cornea join, the knife is substituted and the cornea split. One can easily determine when the cornea has been reached by its bluish appearance. The same technique for splitting the cornea in a sclerocorneal trephine is recommended as in the resection for corneal scar. If properly done it requires less than a minute's time.

In exposing the muscle tendons for advancement recession or enucleation the capsule of Tenon should be disturbed as little as possible and none of it lost. Make the incision in the conjunctiva large enough for freedom of operation for a large incision heals just as easily and quickly as a small one. When the area to be explored is sufficiently exposed remember that immediately under the conjunctiva and over the capsule is some loose connective tissue which will be grasped by the forceps instead of the capsule if it is not pushed aside. To accomplish this place the flat fixation forceps so that the blades will be closed and parallel to the length of the tendon press it down on the globe and at the same time, separating the blades while still maintaining the pressure. It is necessary that the forceps have

a strong spring in order to do this properly. Then, without releasing the pressure, separate the blades about 2 or 3 millimeters and then make increased pressure against the sclera so as to indent it while closing the blades. The forceps will now have a good hold on Tenon's. Keep the grasp firmly make a snip with the scissors close to the end of the forceps while pulling it slightly away from the sclera keep the original grasp on the capsule until the hook has been slid under the tendon. The reason the blades must be kept parallel to the length of the tendon is that when the eye is rotated to expose the area, the capsule, as well as the tendon is put on a stretch which makes it easy to be grasped thus and very difficult if it is attempted against the stretched tissue.

The average distance for the attachment of the recti muscle tendons back of the limbus is, medial 5.5 millimeters inferior 6.5 millimeters lateral 6.9 millimeters superior 7.7 millimeters. Hence, the forceps must be placed far enough back to catch the free side of the tendon. Of course, these measurements vary considerably and, according to Metals they may be as far back as 7 millimeters for the medial and 11 millimeters for the superior. It is better to allow for the maximum than to get too far forward. It is also well to bear in mind the width of these tendons so that in first placing our forceps in position we will not include any of the tendon fibers. The average breadth of the tendon varies from 9.2 millimeters for the lateral to 10.75 millimeters for the superior. Thus one sees that in placing the forceps it is well to be about 6 to 7 millimeters beyond the estimated center of the tendon to be exposed. While the medial rectus is thickest and strongest, its tendon is also the shortest, averaging less than 4 millimeters in length while the lateral, which is the weakest, is nearly 9 millimeters long. It also must be noted that the lines of insertion of the tendons are not straight, but are curved, or even wavy and do not lie parallel to the corneal margin. For example, it is easier to approach the tendon of the superior rectus from the medial side than from the temporal since it is several millimeters closer to the limbus nasally.

The superior oblique attachment to the globe lies just behind that of the superior rec-

tus. Therefore, all one has to do to expose the superior oblique tendon is to engage the attachment of the superior rectus tendon with the hook, reverse the pull by turning the hook and draw the hook backward, thus engaging the tendon of the superior oblique and pulling it forward into the conjunctival wound.

Since the inferior oblique arises from a small depression on the orbital floor just within the inferior orbital margin lateral and close to the nasolachrymal canal, it can be easily exposed by a deep incision into the lower conjunctival sulcus deep enough to strike the perosteum on the floor of the orbit, introduce the hook into the opening until it strikes the floor and then sweeping it nasally until the resistance of the attachment is felt whereupon it is drawn into the wound.

Stitches for a recession are placed where the sclera is thinnest. Fortunately the stitches in this case need not be and should not be as deep as for advancement, for there is less pull on the muscle operated upon after than before the operation for two reasons. First, because the tendon is set farther back, and because the muscle is partly paralyzed from handling. If all of these rules are followed out, bearing in mind the anatomical features mentioned, the tendon of any of the muscles, either straight or oblique can be caught with the first sweep of the hook. Failure to do so means faulty technique.

The attachments of the capsule of Tenon to the margins of the orbit prevent the muscles from entirely retracting and, even when the globe has been removed gave them bases to act upon, thus preserving some motility in the stump. Rough handling of these attachments so as to mutilate these parts of the capsule can result in an ugly proptosis after a strabismus operation or sinking of the globe after enucleation. When a part of the capsule known as the suspensory ligament of Lockwood is mangled the eyeball drops or there may be excessive lateral rotation of the globe or upward movement. Instruments should always be sharp so that clean cuts can be made with the scissors instead of tears. Clean cuts heal easier and are less prone to infection.

O'Connor suggested a novel method of increasing the effect of the Himmelsheimer oper-

ation by utilizing the nasal third of the rectus muscles, turning them under the rectus tendons before sewing them laterally. The objection to this, however, is that it puts even a greater stretch on these transposed portions. A more secure method is suggested for this valuable conception utilizing the paralyzed, split rectus to attach to the vertical recti and then severing the nasal third of their attachment to the globe. This involves the same principle as the O Connor method is easier to execute and eliminates the danger of tearing loose of the vertical strips.

In operating on the muscles in order to obtain complete anesthesia, it is necessary not only to instill an anesthetic in the conjunctival sac and inject the intramuscular cone but also to use a very fine needle and inject a drop or two into the muscle belly itself. While most of the sensory nerve endings terminate near the tendinous attachment, the tendon tissue is too dense for it to spread and complete absence of pain will be accomplished only by injecting into the muscle itself.

In a recent article on "Guides to Choice of Operation for Squint" Sugar stressed Biel schowsky's guide to choice of operation based on anatomical and physiological principles. They are important enough to repeat here.

- 1 When a difference in the two eyes under cover can be determined, the eye showing the smaller deviation is the paralyzed one.

- 2 When the vertical deviation of the paralyzed eye is greater in adduction an oblique muscle is involved (because the obliques help in adduction) and for the same reason when it is greater in abduction a vertical muscle is involved.

- 3 The image of the paralyzed eye is always seen in the direction in which the affected muscle should move the eye.

- 4 When tilting of images is marked and tipping of the head greatly increases diplopia, an oblique muscle is nearly always involved.

- 5 The principal action of a muscle should always be considered.

Klein in investigations concerning the lens capsule and its importance in the technique of intracapsular cataract extraction emphasizes the fact that the zonular lamella is a very thin membrane that covers the peripheral parts of

the anterior lens capsule and is easily separated from it. The posterior capsule is thinner than the anterior lens capsule, the central area of each is thinnest, the maximum thickness being between the equator and the center. In old age the zonular fibers become fragile and the capsule thicker (there is an exception, that of the Morgagnian where both become thin). By a special method, he found that the capsule can resist a pressure of 150 to 200 millimeters of mercury. He recommended traction on the lens capsule and simultaneous pressure at the limbus with a hook to rupture the zonule then, repetition of the maneuver in a different direction. In intumescent and hypermature lenses, as well as in those cases where there has been a previous uveitis, the zonule is so weakened that it is ruptured with a minimum amount of pressure so that the lens can be extracted by the Smith method without touching the capsule. These are the only cases where the Smith method is recommended.

Since the lens capsule is thickest between the center and the periphery this is where it should be grasped with the Arruga or similar forceps in breaking the zonule. There is a tendency of many surgeons in order to make sure of securing a firm hold on the capsule, to take too wide a bite. When this is done it stretches the capsule to such an extent that it is more liable to break before the zonule ruptures. The zonular lamellae may extend back as far as the ora serrata and if pulled upon too much can detach the retina or pull a hole in it. This may occur in doing an intracapsular, or even in doing a needling if not done properly. The lamellae may not attach and there may actually be a thickened capsule around the edge of the lens which may desquamate into the anterior chamber and cause glaucoma.

The anterior hyaloid has tremendous stretching qualities and may come forward after the cataract incision and be mistaken for vitreous. If the speculum be immediately removed and traction made by pulling down on the upper lid, it usually retracts and one may proceed with the operation. Here is another advantage of having lashes with which to grasp the upper lid in order to pull it away from the globe. There may be an anomalous

union of the anterior hyaloid with the lens capsule which proves a detriment to extraction in the lens capsule for in this case the hyaloid is torn and vitreous exudes. This anomalous condition cannot be determined beforehand.

In the embryo there is a sinus running around the pupillary area and in adult eyes cysts sometimes form in this sinus area separating the pigment layer. They may manifest themselves by floating down in the pupillary area as a black mass when we may assume that it is a cyst. If however the black mass is seen at the base of the iris melanoma must be suspected.

Tags near the base of the iris show a relation to the pectinate ligament in lower animals. Normally in the human there are only a few trabeculae in the angle. These may extend from a peripheral iris knob which at times is present in the human. If present in a glaucomatous eye the synechiae will run from it to the angle.

The vessels of the iris run parallel with the radiations. Hence cutting the iris in the direction of the fibers in an iridectomy causes less bleeding and, at the same time, enables one to make a deeper iridectomy. For this reason I fail to see how a peripheral iridectomy in acute glaucoma can be as effective as a complete one, as claimed by some.

Sugar stresses the importance of knowing the depth of the anterior chamber in glaucoma and describes a method for measuring it by means of the McNair Bettman portable slit lamp. The important thing is the angle. Of special significance is the condition of the angle, which can be determined by gonioscopy. Through this means Barkan has developed the operation of goniotomy for congenital glaucoma, which consists of removing or cluding fetal meshwork from the angle promising much for this hitherto almost intractable disease. Anderson's analysis of 84 specimens,

finding the canal open in 75 per cent of the early specimens and no trace of it in children over 2½ years of age, none of which had been operated on strengthens Barkan's warning for early operation in these cases, since the distention of the eyeball tends to obliterate the canal. Barkan makes the distinction between goniotomy in the infant, which consists of removal of fetal remnants from the angle versus trabeculotomy in the adult, whose object is to incise the angle wall that is, the trabeculum itself. In the May issue of the *Archives of Ophthalmology* an article appeared by Hughes and Gartner in which they recommended the removal of the aqueous, substituting air thereby deepening the anterior chamber so that it is possible to perform goniotomy in cases with a shallow chamber as well as in those cases with a wide angle.

described by Krinsky. A prism is held in front of the fixing eye with the apex toward the nose in a convergent squint. This causes the eye to shift toward the nose to resume fixation and the squinting eye will make a corresponding shift away from the nose. Thus using the fixing eye as a handle, and varying the size of the prism the squinting eye can be moved back and forth until the corneal reflex is accurately centered. This is exactly what is done with a Priestly Smith tape but the prism reflex test is considerably simpler to use. It can be used only for monocular squints. The perimeter is still the best method for obtaining distance measurements on a patient with poor fixation in one eye.

As soon as the child is old enough to operate (3 to 5 years of age) and if both eyes are capable of fixation the cover test of Duane is the method of choice for measuring squint. This method has been admirably set forth in the writing of the late James W. White. It will do all that he has claimed for it and we should all learn to rely on it very largely in the measurement of squint.

TREATMENT

Regarding the actual treatment of strabismus, it hardly seems necessary to urge that these children be seen as early as possible after 6 months of age. Unfortunately some pediatricians still advise waiting to see if a deviation will be outgrown but I believe that their number is diminishing. Possibly not much will be done in the way of treatment until the child is a year old but it is worth while to see him earlier to watch developments. Occasionally operation will be indicated as will be discussed later. Whatever therapeutic measures may be required it is undeniable that the earlier they are employed the more complications, such as amblyopia, abnormal retinal correspondence and muscle changes will be avoided or minimized and the chances will be better for binocular vision and fusion.

I believe that there is general agreement as to the value of giving glasses that fully correct any significant hyperopia or astigmatism. The accommodative squints do not often appear before 2 years, but the glasses should be worn as early as possible.

Amblyopia. In this air minded age good visual acuity in both eyes has become even more essential. This means that the correction of amblyopia ex anopsia is the responsibility of the ophthalmologist. Such correction can be accomplished in the majority of patients under 8 if time is taken to impress parents with its importance. Again the earlier occlusion is begun the more quickly will the result be obtained. As mentioned above, it is not necessary to wait until the vision can be measured to know that you are dealing with amblyopia. If the squint is solidly monocular you can assume that the squinting eye is amblyopic and proceed with occlusion. By watching the behavior of the eyes when the occluding bandage is changed, one can proceed with confidence and safety. As long as the originally fixing eye resumes fixation whenever the bandage is removed, the objective has not been achieved. In young children, it is easy to cause fixation to shift to the previously squinting eye, an event that distresses the mother but pleases the doctor because it proves that both eyes are sound. There is no way to differentiate amblyopia ex anopsia from a true amblyopia in little children so all patients should have a trial course of total occlusion for at least 2 months. At the beginning of occlusion anything short of total occlusion 24 hours a day is apt to be a waste of time. It is easier for the child to have it on all the time it will bring the result most rapidly. A firm adhesive bandage over cotton, is the occluder of choice. Later and this will vary from 2 to 8 weeks or more, various occluders can be used on the glasses, but I rely largely on atropine in the better eye with paper on that spectacle lens. It should be apparent that atropine alone will be successful only in cases of slight amblyopia or extreme hyperopia when combined with an occluder on the spectacles, the drug will only succeed after the squinting eye has acquired the ability to fix.

ORTHOPTIC EXERCISES

It is extremely difficult if not impossible to get an idea of the true value of orthoptic exercises from the literature. There is no way to reconcile the highly optimistic report of results obtained by Berens and his associates

with the completely negative report of Fowler, both are competent reporters but they cannot possibly both be right. Unfortunately in the majority of articles reporting indications for orthoptic exercises and the results of orthoptic treatment, definitions and classifications of cases are either absent or so indefinite that few conclusions can be drawn. There is yet no unanimity about the value of orthoptics. In the opinions of many ophthalmologists, it has failed to achieve an established position in the treatment of squint. Yet it is being used by far too many reliable clinicians to be ignored.

It has not been my practice to use orthoptic exercises routinely in healing strabismus. This decision was reached after experience gained while in charge of an orthoptic Clinic at Vanderbilt Clinic, in New York, from 1935 to 1938 while serving on the American Orthoptic Council for several years and from reading the orthoptic literature closely. There are two principal reasons for my decision. First, it was not possible for me to predict the outcome of orthoptic training with sufficient accuracy to feel justified in prescribing it for my patients. No doubt there are orthoptic technicians who can make fair prognostications of their own management of these cases. However if an ophthalmologist is going to use this method of treatment, he too must be able to tell his patient approximately what he has a right to expect in a given time. At the present time I am unable to do this.

My second reason is that I do not have the facilities for carrying out the treatment. Most of us do not have a sufficient number of muscle cases to employ a full time technician. The obvious solution is for several ophthalmologists to pool their cases and resources and set up a technician in a separate office. This has been done in a few cities with notable success but, at present, I know of only one technician in New York to whom private patients can be sent. As you may surmise, she is far too busy to do more than see an occasional case for any one doctor.

In spite of other practical obstacles there is no doubt that there is value in orthoptic exercises, that some patients with accommodative squint would get rid of their glasses more quickly and more certainly with training that

some patients with small deviations could avoid operation and more patients could achieve binocular single vision with fusion after operation. We need to learn a great deal more so that we will know which cases offer reasonable prospects of success and so that accurate prognoses can be given to our patients. In this direction, I hope to see many new orthoptic clinics established.

Age and indications for operation. In recent years the trend in this country has been toward earlier operation until it is now not uncommon to do the operation while the child is in the neighborhood of 1 year of age. These early cases are of course those born with the squint, which means a true muscle anomaly. These are nearly all marked deviations with frequently a vertical complication. While refractive errors can hardly play a part at this age it is probably wise to do retinoscopic and fundus examinations, under ether if necessary. It is usually apparent that nothing but surgery will correct the deviation. The parents are distressed and embarrassed over the appearance of their baby. The avoidance of secondary muscle changes and the chances of re-establishing binocular vision, all greatly outweigh the disadvantage of operating without a complete analysis of the case. This analysis could be gained only after long delay.

In the larger group of cases that come on gradually after the second year and have more or less relation to accommodation operation should be delayed until other measures have been tried. Glasses should be worn for several months amblyopia corrected and possibly there should be orthoptic training. When these measures have been carried out, abandoned or considered unsuitable, operation is indicated regardless of the age. However, for psychological reasons great effort should be made to complete the essential preliminaries and to perform the operation before the child enters school. For the same reasons it may be desirable to shortcut the preliminaries in some cases and operate earlier. A serious objective to orthoptic training is that valuable time may have to be lost in waiting for the child to attain an age when exercises can be given.

Only in those cases with high hyperopic errors (usually $+4$ or more) where the deviation

is largely eliminated by glasses, should the operation be postponed indefinitely. The majority of these children will not require operation and at around 15 years they will be able to remove their glasses when not doing close work. When the occasional operation becomes necessary only that portion of the deviation remaining when glasses are worn should be corrected. Care must be taken not to weaken convergence unduly.

Choice of operation. It is almost impossible to tell someone else what procedure to do for a given deviation. Each surgeon must decide which of the many modern techniques makes the most sense to him and which he can do best. Exactly similar results can probably be obtained in several ways. Mention of a few general principles may be helpful. For the usual concomitant esotropia which measures a little greater for *near* than *distance*, a resection of the externus and a recession of the internus of the same eye are my choice. I operate on the squinting eye because it makes sense to the parents and the muscle changes will be in this eye. If there is a conspicuous overaction of the inferior oblique of that eye, a recession of this muscle at its insertion is done at the same time. Even if the overaction is bilateral, the inferior oblique of the fixing eye need not be touched as its overaction rarely becomes manifest. When the deviation is greater for *distance*, emphasis is placed on the resection of the externus when much greater for *near* the recession of the internus is stressed, or possibly divided between the two eyes. In alternating esotropia, it seems logical to operate on both eyes and while this would probably give the best result, it is not practical to operate on 4 muscles when not absolutely necessary so I would handle them like the monocular squints. An exception to this is the very young alternator who uses the right eye to look to the left and the left to look to the right, and never abducts either eye. Here, bilateral recessions of the interni are indicated. In alternators there will frequently be bilateral overaction of both inferior obliques. If these are approximately of equal amounts and not extreme, they can usually be ignored.

The question of how much to do to correct a given deviation is constantly asked by the

Residents. The best suggestion that I can offer is the figure that Dunnington and I reached several years ago when we analyzed a fairly large series of our operations. We found that when we did a 10 millimeter resection of the externus and a 4 millimeter recession of the internus, on the same eye, we averaged 40 diopters of correction. This is only a rough guide but it provides a starting point.

While I do not want to stress technique because I believe that the many minute variations that have been described are unimportant, I do want to make an appeal to each surgeon to perfect his own technique. It is important that he be able to reproduce an operation with precision as that is the only way that he will be able to find out just what his operation will do. Eventually he will be able to translate accurate measurements into definite, predictable surgical results. I have been using the resection described by Lancaster for several years. Being able to tie the 2 mattress sutures while the tendon is still held firmly in the muscle clamp appeals to me as safer and more definite than other methods. For the recession of the internal rectus, I use two single arm sutures one in the upper third of the tendon secured by passing the needle through the tendon a second time, and the other in the lower third of the tendon both placed as close to the insertion as possible. Great care is used at this point to waste as little of the tendon as possible. The sutures are then passed through the superficial fibers of the sclera, a measured distance from the stump and at least 8 millimeters apart so as to spread the tendon flat. The conjunctiva is closed with care 3 to 5 interrupted sutures being used. The recession of the inferior oblique is done by the method described by White (9). It seems to offer the best possibility for a graded weakening of this muscle. Avertin and ether anesthesia is routine. No 0000 plain catgut sutures on atraumatic needles are used throughout. I bandage only the eye operated upon and do not use atropine. The bandage is changed on the second operative day and removed entirely on the 4th or 5th. These details are mentioned only because they may be of interest, not because I believe that they are necessarily the best.

SUMMARY

Early examination by means of the symbol E to test vision, and measurement of the deviation by means of the corneal reflexes and the prism reflex test are emphatically recommended.

Treatment should start as early as possible and should include occlusion in all cases of monocular squint.

The reasons for not using orthoptic exercises routinely are stated.

Operation can be done safely at 1 year and in certain cases gives definite advantages when done early.

The indications for operation have been discussed and my choice of operations has been given briefly.

A NEW TYPE OF BASKET IMPLANT FOR USE AFTER ENUCLEATION

NORMAN L. CUTLER, M.D., Wilmington, Delaware

CONSIDERABLE thought has been given recently to the possibility of improving the cosmetic result in enucleation or evisceration procedures. It is probable that out of this interest will come improvements that will stand the test of time and use.

The ideal cosmetic result should achieve the following

- 1 Wide range of co-ordinate movement with the remaining eye.

- 2 Instantaneous movement over a short range.

- 3 Normal lid contour i.e. (a) no sagging of lower lid (b) no sinking in of upper lid.

- 4 Permanence of the implant. This implies that it shall not migrate or be extruded.

No procedure, whether enucleation or evisceration, with or without an implant has achieved all of these results up to this time. Different procedures have been devised as recently revealed by Dimitry that have resulted in a good movement of the stump but the problem has always remained of transmitting this movement to the prosthesis. The basket type implant to be described is a step toward improving the transmission of this movement from the stump to the prosthesis on what might be called conventional lines, i.e. the prosthesis is completely enclosed in tissue.

The purpose of a basket implant, with a resulting depressed area in the socket, is to give the prosthesis, which has a stud projecting posteriorly (Fig 1) a grip on the stump. This necessitates, of course, a custom-designed prosthesis and, in addition, imposes new problems of design on the artificial eye maker. This is due to the fact that there is more ability of the cuplike depression to move the artificial eye than there is space in which the eye can move. Thus, it is necessary to adjust carefully the

size and shape of the prosthesis in order to use the minimum amount of space and still maintain a normal fissure. This is facilitated if no attempt is made to fill out a depressed upper lid with the prosthesis, but that is left to the surgeon.

The standard basket now used is shown in Figure 2A and B. It is made of lucite (methyl methacrylate) and measures 11 by 15 millimeters. This size seems to be the best whether the eye to be enucleated is large or small. The anterior edge is slightly thickened the sides of the basket are fenestrated to allow for invasion of tissue. In addition, there are 3 holes in the bottom, measuring 1 millimeter in diameter 2 of which are for sutures. Larger and smaller baskets have been tried but a tendency to reduce movement has resulted in either case. Other materials are being tried, but lucite has been found satisfactory up to the present time. A lucite button, measuring 5 by 8 millimeters, with four 0.8 millimeter holes (Fig 2C) is used to tie the sutures through and maintain the depression during healing. Three double-armed sutures are used black No 0 nylon, blue No 00 dermal and purple coarse dermal. These are used because of their greater strength and smoothness, allowing sutures to be pulled up without breaking. They are of different colors to permit ready identification. One inch (2.5 cm.) straight intestinal needles are used to allow their passage through the plastic button.

At the end of the operation a special plastic retainer (Fig 2D) is placed inside the lids after the method of Gifford. This greatly reduces postoperative edema, keeps the basket centered, and completely prevents any prolapse of the conjunctiva. The average operating time for this procedure is the same as for any implantation procedure, namely 22 to 25 minutes.

Two baskets slightly smaller than the standard have been placed inside the sclera after

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

Fig. 1 Plastic prosthesis showing projecting stud on posterior surface.

evisceration. No advantage accrued as far as movement of the stump was concerned and the depression into which the stud of the prosthesis fits was considerably smaller. In addition, there was extreme postoperative edema involving the entire side of the face which lasted 7 to 10 days. I have seen 2 cases in which a ball implant was placed in the sclera with extremely good movement practically as good as that of the normal eye but because of the smooth contour only a small amount could be transmitted to the prosthesis.

The muscles are not sutured in this procedure. Figure 3 shows the posterior view of a basket implant removed at autopsy 8½ months after operation from a patient who was killed in an automobile accident. It will

be seen that all the muscles including the obliques are attached near the rim of the basket.

OPERATIVE PROCEDURE

Anesthesia is induced by intravenous injection of sodium pentothal and retrobulbar injection of 2 cubic centimeters of 2 per cent procaine hydrochloride.

The eye is prepared in the usual manner. A speculum (Weeks) is inserted, the conjunctiva dissected from the limbus, and the dissection carried to the fornices in all directions. The rectus muscles are then isolated and cut free from their insertions. The conjunctival opening usually is enlarged nasally and temporally about 2 millimeters to permit passage of the globe. The globe is grasped with fixation

Fig. 2. A, Top view of lucite basket; B, side view; C, lucite stud; D, posterior view of lucite with central depression for stud.

Fig. 3. Posterior view of basket, implant removed at autopsy 8 months following implantation showing muscles attached to anterior edge.

forceps at the tendon of the internal rectus muscle and the nerve cut with enucleation scissors. The prolapsed globe is then freed from the oblique muscles and removed.

A dry gauze sponge and a little pressure usually reduce the bleeding quickly to enable one to inspect Tenon's capsule (Fig. 4).

The basket with one black nylon suture, size No. 0 fitted with two straight 1 inch

Fig. 5. Basket with No. 0 black nylon suture inserted. Suture carried through Tenon's capsule and conjunctiva at 1 and 6 o'clock.

Fig. 4. Tenon's space exposed, ready for insertion of basket implant.

intestinal needles, is then placed in Tenon's capsule (Fig. 5). The upper suture is brought through a firm bite of Tenon's capsule at 12 o'clock and out through the margin of the conjunctiva. The lower suture is brought out similarly at 6 o'clock.

A blue No. 00 dermal double-armed suture with 1 inch intestinal needles is then carried through Tenon's capsule and the conjunctiva about 2 millimeters on either side of the black suture which was placed at 6 o'clock (Fig. 6A). Each suture is then carried through in a simi-

Fig. 6. A, Blue dermal mattress suture, carried through Tenon's capsule and conjunctiva on either side of black nylon from within outward and finally through Tenon's capsule and conjunctiva 12 and 6 o'clock.

lar manner at 12 o'clock. The suture on the right side is now carried through Tenon's capsule and the conjunctiva at 3 o'clock on the same side and the suture on the left at 9 o'clock.

A purple dermal (coarse) double armed suture, similar to the blue dermal suture is now placed about 2 millimeters on either side

Fig. 9. A. Suture, 2, pulled up, imbricating Tenon's capsule and conjunctiva vertically. B. Suture 2, tied and cut. Suture 3 pulled up tight and cut through, imbricating Tenon's capsule and conjunctiva horizontally and closing the basket opening.

Fig. 8. Button holder

of the blue suture at 3 o'clock, the needle taking similar bites of Tenon's capsule and coming out through the conjunctiva. These two sutures are now carried across above all other sutures and brought out 2 millimeters on either side of the blue suture at 9 o'clock (Fig. 6B).

These two mattress sutures (blue and purple) are placed as outlined in the preceding paragraphs so that when they are pulled up they cause a double imbrication or folding of Tenon's capsule and the conjunctiva and the black sutures still come out through the upper layer after this has been done. All sutures are carried through the lucite stud, as shown in Figure 7A and B. Sutures 1 and 3 pass through the same two holes and suture 2 through the other two holes.

While the assistant holds the button with the lower end at the level of the rim of the basket with the button holder (Fig. 8) the blue suture is pulled up, tied and cut (Fig. 9A) and then the purple suture is similarly

Fig. 10. Suture 1 pulled up, tied and cut forcing button with Tenon's capsule and conjunctiva down into the basket.

Fig. 1. Plastic retainer.

handled. This pulls Tenon's capsule and the conjunctiva into place and closes the opening.

A single tie is now placed in the black suture and as this tie is gradually pulled up the index fingers make traction and a little pressure. The assistant then releases the button from the forceps. As this tie is pulled tight, it forces the button with Tenon's capsule and the conjunctiva down into the cup. Three knots are placed and the suture is cut (Fig. 10). No conjunctival sutures are necessary.

A lucite retainer is placed inside the lids. An adhesive dressing with firm pressure but with no roller bandage is applied.

POSTOPERATIVE COURSE

The first dressing is done on the third postoperative day, the retainer being removed and

the socket irrigated. The retainer is replaced and if there is still some edema an adhesive dressing is put back on for 2 more days. In most cases the dressing can be omitted. On the fifth postoperative day the sutures and the button are removed. A temporary retainer with button attached (Fig. 11) is placed in the socket at this time. This is removed daily and the socket is irrigated for a week.

In none of the cases in which operation was performed has there been any prolapse of the conjunctiva. This is probably due to the type of operation and to the retainer. In general, there has been little reaction and no discomfort at all after the first postoperative day.

At the end of 2 to 3 weeks, depending on the shrinkage of its tissues, the socket is ready for a custom made prosthesis, similar to the one shown in Figure 1.

COMPLICATIONS

It is important not to pull the sutures beyond the snug state, as otherwise pressure necrosis and exposure of the bottom of the basket will result. This complication will also occur if the button is not removed at the end of 5 days. If exposure of the bottom of the basket does occur, a retainer without a button attached is put in, and granulation and epithelialization will take place in a few days, without impairment of the result. If after the sutures and the button are removed on the fifth post-

Fig. 12. Appearance of socket in patient, 1 month after operation, showing impression in the basket and the range of motion.

operative day there is a thin appearing lining on the bottom of the basket a plain retainer can be used from 1 to 3 days and then a button retainer employed

A sufficiently firm bite of Tenon's capsule must be obtained in placing the mattress sutures, since there is slight tension on the capsule when it is inverted into the basket. In 2 cases in which a ball implant was removed and a basket put in the sutures did not hold. This was also true in a case in which a considerable amount of scar tissue was present—the sutures cut through the inelastic scar tissue. It was necessary in these 3 cases to remove the baskets.

Postoperative hemorrhage has never been a problem in our cases. In the 3 cases just mentioned in which the sutures did not hold because of scar tissue and the basket was removed approximately 10 days after operation, it had to be dissected out. Certainly the basket cannot be extruded.

PROSTHESIS

The socket is ready for the final prosthesis at the end of 2 or 3 weeks. This has been of plastic, made according to the standard Army procedure and under the direction of Captain Stanley F. Erpf and Captain Arthur L. Lund

blad of the Dental Corps of the Army of the United States

The prosthesis is not made from an impression of the socket, since that would result in its occupying too much of the available space. Figure 1 shows some variations in the prostheses that have been fitted. In general, the stud is adjusted to fit into the depression and the base around this stud is cut away to allow the edge of the basket to come forward when the socket is turned. Through support of the stud there is considerable relief of pressure on the tissues in the region of the fornices.

It is not absolutely necessary to use a custom made eye with a stud, good movement can often be obtained with a Snellen form. The reason for this is that the movement of the prosthesis is in part due to the change in the shape of the socket when the basket rotates; one side becomes shallow and the opposite side deep and the eye has to move.

The following tabulations were made on the basis of observations on 60 sockets fitted with artificial eyes. Practically all of them were fitted with custom made plastic eyes. It is realized that this small number may not represent a true cross section. The series was collected from the wards without regard to the preoperative condition. It consisted of 20

Fig. 13 Patient 5 months after operation showing depression and movement of socket.

sockets without implants 20 with ball implants and the first 20 with basket implants.

Average motion degrees	No implant	Ball implant	Basket implant
Nasally	19	9	25*
Temporally	3	5	22
Superiorly	25	20	20
Inferiorly	12	20*	30
Total	60	74	109

The sockets without implants showed the greatest variation in movement from patient to patient and those with basket implants the least variation. This is illustrated by the following tabulation.

Prosthesis having	No implant	Ball implant	Basket implant
45° total horizontal movement	1 of 20	3 of 20	8 of 20
5° total vertical movement	6 of 20	8 of 20	19 of 20

These tabulations do not indicate the action of the oblique muscles which is a prominent feature of the basket sockets. Neither do they indicate the most important characteristic of all that is, the much more rapid response to movement of the muscle cone, with a notable decrease in the time lag as compared with that for the normal eye.

SUMMARY

On the basis of 100 operative procedures, a new type of basket implant for use after enucleation is presented which with a new type of prosthesis, gives more instantaneous movement and a wider range of action. This procedure, combined with use of a plastic retainer eliminates prolapse of implant and shortens the postoperative convalescence period.

RECONSTRUCTION OF ORBITAL FLOOR DEFECTS

ARTHUR E. SHERMAN M.D. Major M.C. A.U.S. East Orange New Jersey

THE floor of the orbit is triangular in shape and is made up largely of the orbital plate of the maxilla. The orbital portion of the zygomatic bone makes up the anterolateral portion and a small portion of the posterior part of the floor is formed by the orbital process of the palatine bone. The anterior margin is thicker and stronger than the remainder of the floor. The inferior orbital fissure is the lateral boundary of the floor and the infraorbital sulcus runs forward along the central portion of the floor from the inferior orbital fissure to the infraorbital foramen which lies about 1 centimeter below the lower orbital margin. The sulcus and foramen transmit the infraorbital artery and the main portion of the second division of the trigeminal nerve that is the maxillary nerve which is known as the infraorbital nerve as it passes into the infraorbital sulcus.

Trauma to the lower orbital margin with resulting fracture of the margin and floor of the orbit not infrequently produces more severe displacement of the thin floor of the orbit than of the thicker and stronger margin itself. The displacement of the floor is usually downward due to the concave orbital surface of the floor anteriorly and because an air space the maxillary antrum lies below the floor. It is Pfeiffer's opinion that fracture of the wall of the orbit is the entire cause for traumatic enophthalmos. Of 53 cases reported by him 24 had a depressed fracture of the floor with out any fracture of the orbital margin. More than half of these were caused by a blow with a fist. Pfeiffer states that in the cases of less severe enophthalmos the posterior portion is fractured and in the cases of more severe displacement the entire floor is broken through. It is surprising how infrequent there is permanent visual damage in these cases. At times severe trauma to and fracture of the supraorbital area may produce an accompanying

depressed fracture of the floor of the orbit due to transmission of the force through the orbital contents. Depressed fracture of the floor may also occur from the explosive force of shell fragments entering the orbit and from actual perforation of the floor by shell fragments or other foreign elements. It is quite unusual to have an elevation of the floor of the orbit unless there has been a severe crushing trauma to the region of the antrum.

A diagnosis of depressed fracture of the floor of the orbit is made on the history of trauma and the presence of depression of the eyeball with some enophthalmos. Diplopia may be present and also anesthesia or hypesthesia over the distribution of the infraorbital nerve. Immediately following the trauma these signs may be masked by edema and orbital hemorrhage. There may even be an initial exophthalmos. Crepitation from air in the soft tissues and palpable displacement of the orbital margin may be evident. Careful stereoscopic x-rays will usually confirm the diagnosis. There may be marked loss of vision due to internal ocular damage or due to compression of the optic nerve by fracture into the optic foramen or by hemorrhage into the optic nerve sheath in the foramen.

When there has been little or no depression of the floor of the orbit no treatment is indicated. When very definite depression is present it should be corrected as soon as the initial reaction has subsided. This is best done by the otolaryngologist by means of a Caldwell-Luc approach with elevation of the depressed orbital floor and moderate packing of the antrum for a day or two. When this is not done a permanent depression of the orbital floor and orbital contents results. Fracture and displacement of the lower orbital margin should also be corrected as early as possible with internal wiring of the fragments or some method of external fixation if necessary.

When there has been a severe compound comminuted fracture of the lower orbital margin it may be necessary to debride some of the

loose bone fragments. This results in more or less subsequent external deformity.

The purpose of any procedure to reconstruct the orbital floor is primarily to elevate the orbital contents. If sufficient correction of this depression is obtained it will also eliminate the sinking or retraction of the upper portion of the upper eyelid and lessen the enophthalmos. In late cases of depressed floor it is not possible to elevate the floor to its normal position because of the firm adhesions which have formed. In the past this has usually been accomplished by the use of autogenous or preserved cartilage grafts to the floor of the orbit under the periorbital. This is the method used by most of the general plastic surgeons during the past few years in the army general hospitals that were ophthalmic and plastic centers. The taking of an autogenous rib cartilage graft makes an additional procedure and at times the pleura has been accidentally perforated. The use of preserved cartilage has been quite satisfactory although it has been demonstrated that preserved cartilage buried subcutaneously produces a typical low-grade foreign body reaction over a period of months and is gradually absorbed and replaced by fibroblastic tissue. Osteoperiosteal grafts from the tibia have also been used. These are used to bridge the defect and usually require temporary additional support by packing in the antrum. This, together with taking of the graft, makes a needlessly complicated procedure.

It was our experience at O'Reilly General Hospital and also the experience of ophthalmologists at some of the other army eye centers, that the use of various inorganic materials has been very satisfactory for orbital floor reconstruction with resulting simplification of the surgical procedure.

In June of 1945 at the suggestion of Dr Reudemann of Cleveland, Lieutenant Colonel Struble at Crile General Hospital used tannum wool and later tantalum mesh to fill in defects of the orbital floor in battle casualties in whom the Reudemann implant eye was being used. Struble stressed the importance of careful preoperative x ray determination of the size of the defect and received excellent cooperation from his roentgenologist, Lieutenant Colonel Shifflet.

During the latter months of 1945 Captain Souders of Dibble General Hospital used rhomboid shaped plates of the plastic acrylic (methyl methacrylate) to cover the defect of the floor of the orbit in old fracture cases who had some depression of the eyeball. Souders used various sizes and thicknesses of these acrylic plates depending on the amount of depression of the eyeball and size of the defect in the orbital floor. The dissection was made through a skin incision along the lower orbital margin but he placed the acrylic plate on the periorbital and not under it. The plate was held in position by sutures through small holes near the anterior edge of the plate and through the periorbital.

About this same time Major DeVoe of Halloran General Hospital used a packing of glass wool under the periorbital in several cases of depressed floor to fill in the defect and elevate the eye and orbital contents. He reported very satisfactory results and no complications.

In the spring of 1945 at O'Reilly General Hospital we began to use a wedged shaped acrylic implant to the floor of the orbit to elevate the orbital tissues in cases of anophthalmos who had had an enucleation with small implant in Tenon's capsule, or who had had a

Case 2

Fig 5 Final result.

Case 3

Fig 7 Final result.

simple evisceration of the eyeball. This procedure proved a quite satisfactory method to eliminate or lessen the retraction or sinking of the upper portion of the upper eyelid. We soon applied this procedure to cases of old fracture of the floor of the orbit with depression of the eyeball and enophthalmos. The acrylic wedges were made in 3 sizes: the average or middle size being about $2\frac{1}{2}$ centimeters by $1\frac{1}{2}$ centimeters and about 8 millimeters thick at one end and tapering down to about 4 millimeters at the other end. The operation is similar to that used by Gilles and others except that the wedgeshaped acrylic implant is used instead of a cartilage graft. After incision through the skin and subcutaneous tissue down to the lower orbital margin, the periorbital skin is incised and the periorbital skin is thoroughly elevated with a submucous elevator. A wedge-shaped acrylic implant is then placed on the depressed floor with the thick end of the wedge posterior. A large enough implant is used to satisfactorily elevate the orbital contents and two or more implants can be used in cases of severe depression of the floor. Traction sutures in the tendons of the lateral and medial rectus muscle are a great aid in drawing the eyeball upward and forward at the time the wedge is being inserted. The periorbital skin is firmly closed with No. 000 gut mattress sutures. Subcutaneous sutures should also be used to avoid a depressed postoperative scar. A good pressure dressing is important to prevent or lessen hematoma.

Gilles was one of the first writers to recommend the use of cartilage grafts for replacing loss of bone of the orbital rim. This has been used extensively since that time. Landemann in 1916 first described the use of an iliac bone graft to the mandible and this was later ap-

plied to the malar and infraorbital area by a number of plastic surgeons.

During the past few years tantalum plates, tantalum mesh, and acrylic plates have been used to replace loss of orbital margin. Too frequently the preformed tantalum or acrylic plate does not give the proper contour to the overlying tissues. It is difficult to alter these plates satisfactorily at operation. Also it is not a simple procedure to fashion the plate. Tantalum mesh is easily shaped at the operating table but it does not become firmly attached to the surrounding bone. Rib cartilage grafts do not become attached to the bone and also may change after operation. It was the experience of the eye and the plastic service at O'Reilly General Hospital that these inorganic materials and also cartilage grafts did not give as satisfactory results in reconstruction of the lower or lateral orbital margin or malar area, as did the use of grafts of iliac bone. After removal of most of the cortex the cancellous bone can be easily shaped to fill in the defect properly and give a very satisfactory contour to the overlying tissues. If the ends of the graft rest on exposed bone it soon becomes firmly attached to this bone. A blood supply is rapidly formed into the grafted bone and a cortex or pseudocortex forms on the surface of the graft. Postoperative hematoma will seldom cause trouble if a narrow rubber

Fig 8.

Case 4.

Fig 9.

Fig. 15. Appearance on admission

Fig. 16. Before bone graft.

Fig. 17. Result.

CASE 5 (Figs. 10, 11 and 12) Patient was struck in the right orbital area with a large stone and incurred severe compound depressed fracture of supraorbital area and of the floor of the orbit. Débridement of frontal sinus area and repair of lower eyelid performed at another general hospital. Admitted to O'Reilly General Hospital 3 months later. Severe enophthalmos and depression of right eye as well as marked depressed deformity of supraorbital area were present. He had loss of central vision due to traumatic damage to macular area. One month after admission the eye was quite well elevated and the enophthalmos fairly well reduced by means of five acrylic wedge implants to the depressed floor of the orbit. Recovery was uneventful. Two months later an iliac bone graft to the supraorbital area was performed by Lieutenant Colonel Karlson.

CASE 6 (Figs. 13 and 14) Patient incurred a compound comminuted fracture of right zygoma and severe laceration of right eye from shell fragment wound. The right eye was enucleated 3 weeks later and 1 month following that a large cheek flap rotated to fill defect over zygoma region. He was admitted to O'Reilly General Hospital 6 weeks later. There was a long broad depressed scar from lateral lower orbital margin down to angle of jaw with loss of malar eminence and of lateral lower orbital margin. The lateral canthal area was drawn down about $\frac{1}{2}$ centimeter. Three months later an iliac bone graft was used to reconstruct the lateral lower orbital margin and malar area, with excision of much of the scar. Two months later the lateral canthus was elevated by means of a Z-plasty or interposition of flaps.

CASE 7 (Figs. 15, 16, and 17) Patient incurred severe compound comminuted fracture of right zygoma and maxilla with avulsion of lower eyelid and anterior segment of eyeball from shell fragment. The wound was debrided the same day. The eye was eviscerated 5 days later. He was admitted to O'Reilly General Hospital 13½ months later. There was a loss of entire right lower eyelid with conjunctiva and skin adherent to the remains of lower orbital margin. Due to fracture of the floor of the orbit there was marked depression of the orbital contents. Several operations were used to reconstruct the lower eyelid and the area of the lower orbital margin was reconstructed with an iliac bone graft. After the eyelid fissure was reopened the orbital con-

tents were elevated by means of an acrylic wedge implant on the floor of the orbit. A fascia lata graft was used to correct the retraction below the brow.

SUMMARY

Fractures of the floor of the orbit should be reduced soon after injury if feasible.

When late reconstruction is indicated the orbital contents can be very satisfactorily elevated by means of an acrylic implant on the depressed floor. Other materials such as tantalum mesh and glass wool have been satisfactory in the hands of some surgeons.

Small losses of the lower orbital margin can be satisfactorily filled by a fascia lata graft. Larger losses are best reconstructed by a graft of cancellous iliac bone with more consistently good results than cartilage grafts or preformed tantalum or acrylic plates.

THE RECONSTRUCTION OF THE UPPER LID

EDMUND B SPAETH M.D. F.A.C.S. Philadelphia, Pennsylvania

WHEN considering this subject, 'The Reconstruction of the Upper Lid' almost every person who has had experience with ophthalmic plastic surgery will immediately think of some more or less complicated case in the correction of which he had a part. The difficulties and complexities of such individual cases are most stimulating—of this there is no doubt. Nevertheless such cases as all others are corrected through certain basic principles peculiar to the subject, and common to all these conditions.

Regardless of any one technique these principles can be divided into two major subdivisions—when reconstructing an upper lid is a good functioning eyeball present, and is the socket surgically anophthalmic? These two possibilities modify the surgery necessary to a tremendous degree.

A second group of three probable conditions which influence the necessary surgery and contingent upon the first subdivision are the eyelid defects themselves. First, is the deformity under treatment the result of the loss of the external layers of the lid only with normal conjunctiva present second in the case considered are all the structures of the lid both anterior and posterior surfaces, wanting even partly and third are only the posterior lid surfaces and structures predominately deficient?

The presence of an intact functioning eyeball in lid reconstructions compels, without permissible modification the use of conjunctiva or of mucous membrane for the reconstruction of the posterior surface of either lid. The absence of an eyeball, that is surgical anophthalmos, permits the use of epithelium either as a free skin graft or as some type of pedicle flap for replacing the lost posterior surface of the reconstructed lid. The reconstruction of a lid in cases in which no eyeball

is present is a simpler procedure because demands are less exacting. Even the question of later lid motility is relatively insignificant, because corneal exposure and difficulties from that are not a problem. As a matter of fact in many of these cases the ideal result hoped for is that of good looking fixed lids which will retain a prosthesis satisfactorily even though they may be quite immobile.

A third consideration of importance in the reconstruction of a lid especially the upper lid is a thorough knowledge of the rather complex anatomy of this lid. Surgical principles which are harmonious with the anatomy of the upper lid are certain to give much better results than any technique which disregards this anatomy. One must remember that the lid has two major parts—a posterior conjunctival and tarsal plate surface or layer and an anterior muscle and skin layer. The muscle pull of the levator palpebrae superioris is at a right angle to the muscle action of the orbicularis fibers. The two muscles lie in entirely different planes. These two muscles are not only antagonistic, one to the other but both are very active muscles. Last the two canthal angles are themselves quite immobile but here the two muscles have common attachments.

Reconstructive surgery for the correction of defects in the posterior surface of the lids is essentially the reconstruction of a cul-de-sac by means of mucous membrane. Cicatrices may be present simultaneously in the external surface of the lid, which needs reconstruction and resuture but this is a minor part of the surgical procedure. A free graft of mucous membrane sutured into a correcting position is the basic essential (Fig. 1).

This same situation, when present with surgical anophthalmos means a necessary correction either with the same type of graft or by means of a free skin razor cut graft. This must be cut as thin as is humanly possible. In these instances the external surface

Fig 1. Mucous membrane correction of the posterior surface of a defect of the lid.

Fig 2. Simultaneous correction of posterior and anterior surfaces of the upper lid. Prosthesis in position.

Fig 3. The major portion of the upper lid is lost with much cicatrix present. The entire superior cul-de-sac is absent. A pedicle flap from the forehead and a free skin graft to the posterior surface of the lid.

of the lid which is deficient may be corrected simultaneously with either a pedicle flap or a free skin graft. Figure 2 is such a case. The superior cul-de-sac of the deficient socket was corrected by mobilizing the remains of the upper lid still present, swinging these inward upon themselves as a hinged flap to form the new posterior surface of a new lid. At the same time, the anterior surface of this lid was corrected with a free skin graft. It is in this type of case that the use of supraclavicular skin has such impressive successes. Figure 3 is a similar case in which the correction of the external surface was achieved by means of a pedicle flap from the contiguous regions. A free razor cut epithelial graft was placed on the posterior surface of the lid flap. A pedicle flap had to be used here because of the extensive scar in the tissues remaining. To remove all of that meant the removal of almost the entire lid. In general pedicle flaps are to be

used only when necessary, never as an operation of election. When that is so as in this indication there need be no hesitancy about their use. If properly executed the additional scarring which they cause can be held to a minimum often to an amount quite inconsequential. The value of a pedicle flap lies in the ability to transplant larger portions of epithelium under difficult circumstances (anatomic, naturally) with a greater chance for continued viability in the graft than if that same amount of skin had been transplanted freely and without this added means for nutrition, i.e. the pedicle.

The ideal reconstruction of an upper lid in the presence of a normally functioning eyeball assuming that both the anterior and the posterior surfaces of the lid have been lost in part depends upon a technique originally advanced by Landolt in 1901 and subsequently carried to even greater general

Fig 7 The complete correction of the upper and lower lids by an epithelial lined flap

form a smooth lid margin. That tarsus which formerly lay in the lower lid will now be in part, if not wholly, in the upper lid. The conjunctival surface of the two lids is usually quite adequate for good function. Figure 5 is an illustration of this technique. The entire upper lid was not lost but the major part was missing. The illustration in center shows the intermarginal attachments. The curve of that points out rather clearly the total amount of new tissue now lying into this position. The illustration at right shows the new palpebral fissure following its formation—also the degree of closure possible.

In this case the lashes were suggested by a line of tattoo marks at the new lid margin. A hair bearing graft for the eyelashes of the upper lid can be placed into position rather readily prior to the formation of the new palpebral fissure. Such a graft should be taken from the lower edge of the opposite eyebrow cut with beveled edges and sutured into position.

A second technique to be considered under similar circumstances, i.e. eyelid defect in the presence of a good functioning eyeball necessitates the implantation of a mucous membrane graft into either the forehead or the upper lid immediately beneath the skin surface, to prepare the necessary graft with a posterior mucous membrane layer which will function as conjunctiva. This graft either as a free graft or as a pedicle flap is then transplanted to its correcting position for the simultaneous reconstruction of both the conjunctival and skin surfaces. Figure 6 shows the utilization of this basic principle by means of a pedicle flap. Mucous membrane covers the posterior surface and epithelium the anterior surface. Some of the principles of Wheeler's halving operation will apply in the utilization of this technique. This is so because those principles of Wheeler's are basic with ophthalmic plastic surgery whenever accurate car-

penetry is necessary in lid surgery. They are not characteristic of any individual procedure.

The mucous membrane to be used is taken from the buccal mucosa trimmed to maximum thinness wrapped over a mold, and then buried into a pocket prepared for it. After this has taken surgically any portion of the mucous membrane may be transplanted with any amount of epithelium needed. In the instance shown a certain portion of the lid remains were rearranged and utilized by scar resection and by suture. The case was one of postmalignancy reconstruction. Somewhat less than one-half of the lid was still wanting following that. The mucous membrane epithelium pedicle flap was quite sufficient for a good correction. That portion of the rather conspicuous mucous membrane still present upon the skin of the lower lid had to be removed and the area covered with a skin graft. Skin from the supraclavicular region or from the opposite upper lid are equally satisfactory for this.

Hughes carried out this principle of combined mucous membrane epithelium graft by implanting the mucous membrane into a pocket of the opposite lid. Skin and mucous membrane were then transplanted as a free graft. Even though this technique was successful for the lower lid and perhaps should be

Fig 8. An epithelial lined pocket on the face prior to transplantation for a new upper lid.

Fig. 9. A, left, Deformity of upper lid corrected by scar resection and resuture, also with a necessary enucleation. B 3 months following surgery

recommended for that, the use of a flap is better for an upper lid repair.

The complete correction perhaps better expressed as correction for the more or less complete loss of an upper a lower or of both lids, in the absence of an eyeball is similarly done but with epithelium rather than with mucous membrane. A pocket of epithelium is formed on the forehead or beneath the skin of the upper face. Following that one may transplant a flap having two epithelial surfaces, an anterior and a posterior surface thus making possible correction for the complete loss of one or more lids. The principle is quite like that described in detail for the use of mucous membrane but the absence of an eyeball permits the use of epithelium for the posterior surface of the new lids. Figure 7 illustrates such a case before and after its correction. Figure 8 shows a pocket upon the face before transplantation to an upper lid.

In this presentation the only cases considered for the explanation of the rules for lid reconstruction were those in which there had been a loss of soft tissue to such an extent that the replacement of these tissues was necessary for the correction of the case. Many cases could be presented wherein the correction was obtained by simple (meaning uncomplicated and not ease of performance) scar resection resuture and the reposition of those tissues still present to correct the plastic defect present. Figure 9 is such a case. The necessary enucleation of the phthisical eye had little effect upon the condition of the lid. Scar removal and suture were responsible for the satisfactory result obtained. This possibility as a surgical principle must be remembered in the

Fig. 10. A, left, Extensive ectropion following herpes, the lids opened and closed. B Correction with a rasor cut free skin graft.

consideration of cases for correction. It is properly included herein considering the title of the paper and the scope of its subject matter.

RECAPITULATION AND CONCLUSION

In this presentation such defects as ectropion entropion symblepharon etc., have not been the basic conditions under consideration. The extent of pathology possible in some of these conditions, however as illustrated in Figure 10 might permit one to consider this degree of deformity worthy of the term—lid reconstruction. It is, nevertheless only a case of extensive ectropion and as such is to be corrected by procedures rather well established for this type of condition.

The real purpose of the paper has been to outline the principles underlying lid reconstructions, and especially when applied to the upper lid. The different anatomic possibilities which present themselves for correction differ so decidedly in their demands and hence in the permissible surgical techniques available for correction that it was thought necessary to emphasize again that basic fact.

These surgical principles as they have just been discussed are the result of clinical experience and as such they should be seriously considered as these cases appear for correction.

THE MANAGEMENT OF NONMAGNETIC INTRAOCULAR FOREIGN BODIES

HARVEY E. THORPE, B.Sc. M.D. F.A.C.S. Pittsburgh Pennsylvania

THE character of intraocular foreign bodies coming to the ophthalmic surgeon's attention has changed materially in recent years. Formerly 95 to 98 per cent were magnetic, leaving a bare 2 to 5 per cent of cases to which the magnet was not applicable. Now some series of cases are reported in which the nonmagnetic percent age runs as high as 10 and even 40 per cent.

The ratio of nonmagnetic to magnetic intraocular foreign bodies was always higher in battle casualties than in civilian life. This ratio took a sharp rise with the nefarious introduction by the Axis forces of nondetectable nonmagnetic land mines in the North African Desert campaigns as reported by Stallard (16). The World War II experience of the United States Army Medical Corps is well described in Wilder's report, that out of 150 enucleated eyes received at the Army Institute of Pathology 89 harbored nonmagnetic particles.

The increased use of alloys containing copper, aluminum, brass, lead, zinc, manganese, nickel, etc. in industry as well as war thus presents new and difficult problems. In addition to these one runs across eyes harboring glass, plastics, coal, stone, sand, lashes, grit, wood, and other substances.

Our miracle tool the magnet is worthless in application to nonmagnetic substances. Nor does it attract steel alloys containing considerable manganese. Often the ophthalmologist was thus made to despair on seeing a patient with a nonmagnetic intraocular foreign body. New simplified and improved x-ray and other localization methods with improved surgical techniques have made it possible to save some of these eyes from blindness. Several problems present themselves when one is called to attend a traumatized eye.

1 How shall one proceed in the average case of ocular injury?

2 When should an intraocular foreign body be suspected?

3 How much damage has been done to vital structure?

4 Is a foreign body present within the eye and how can we readily localize it accurately?

5 How does one differentiate the nonmagnetic from the magnetic foreign body?

6 To what extent does infection complicate the picture and how shall we control it?

HISTORY

The ophthalmologist should investigate the possible presence of an intraocular body in every case of possible injury and especially in uveitis. The history is most important. The examiner must question the patient in detail about the likelihood of exposure to injury while hammering, chiseling or working with rotating or moving machinery. One should note whether the patient was near flying particles or near an explosion or in proximity to shattering solids. An investigation of the tools and substances in use at the time of accident gives a clue as to the likelihood of the intraocular particle being magnetic or otherwise. It also may tell us whether the fragments are glass or stone, or copper, or steel, etc.

Stallard (16) writing of his North African war experiences found a clue to the nature of the intraocular fragments by examining small particles lodged in the skin of the lids and face. U.S. Army ophthalmologists have examined injured eyes which contained more than one particle, some magnetic and others nonmagnetic. Close questioning of the patient may further reveal the size of the fragment and its course of flight toward the eye. The lapse of time since injury is necessary to ascertain fragments that have been in contact with soil may harbor tetanus bacilli. These and a host of other details may be elicited by a careful history. Previous negative examinations or the story of removal of a superficial corneal

Fig. Course of foreign body through the globe and trauma caused to a, cornea (perforation) b, iris (arrow points to hole) c, lens (tract through it) d, Section of globe showing tract of particle, location of foreign body and vitreous opacities due to hemorrhage e, Foreign body lodged in retina, as viewed with ophthalmoscope.

particle should not lead us astray. There are many cases on record dismissed with a pat on the shoulder which later turn up with siderosis or chalcosis or a cyclitis due to an intraocular foreign body.

THE EXAMINATION

Both eyes must be examined subjectively and objectively. One may find evidence of disease, of injury or even of sympathetic ophthalmia. Visual acuity and field examination of each eye where possible should be followed by complete examination with all the instruments and methods at our command. The anterior segment must be studied with loupe and oblique illumination, with ophthalmoscope, with the transilluminator and particularly with the slit lamp microscope. The cornea, the conjunctiva, the sclera, the anterior chamber, the iris, the lens, the vitreous, the entire visible retina and the optic nerve must be painstakingly scrutinized. If photophobia or pain interfere a drop of local anesthesia such as tetracain 0.5 per cent may facilitate the examination. A perforating wound in the cornea as evidenced by a hole in Bowman's and especially in Descemet's membrane leaves permanent telltale evidence. A hole in Descemet's membrane or in the iris leaves permanent evidence. Discovery of such, however minute is proof of a penetrat-

ing wound and charges the examiner with an exhaustive study to establish the presence of an intraocular foreign body and to localize that foreign body.

The value of exhaustive routine examination is evident from the next 2 cases cited.

CASE 1. A.T., mechanic, aged 30 years, complained of occasional discomfort and redness of the left eye. Routine examination revealed a minute perforation of Descemet's membrane. A history of injury 6 months previous while chiseling was finally elicited. The patient remembered that a foreign body was removed from the conjunctiva by a fellow workman. Since then his eye watered in bright light, etc. The first x-ray examination was negative. A second x-ray examination by Vogt's soft tissue technique revealed a minute fragment near the iris root. With the aid of gonioscopy it was possible to visualize the foreign body covered by exudate in the lower anterior chamber angle. The particle was subsequently removed and the eye quieted down.

CASE 2. J.B. Auto repairman, aged 34 years, referred with 24 hour old perforation of his left eye by a piece of wire. Examination revealed a left corneal perforation in the pupil zone with swollen traumatic cataract bulging into the anterior chamber.

Vision of the right eye was 20/25. Slit-lamp examination of that eye revealed early siderosis and a healed limbus perforation. X-ray examination of both eyes located a small irregular metal splinter in the right ciliary body. The left eye was negative roentgenologically.

Further questioning revealed a history of injury 9 months previous while working on another job. The first aid attendant and the plant surgeon found no foreign body at that time and since there was no pain and very little redness the eye was dismissed as negative at that time.

The examination gave evidence of a distinct injury involving both eyes: the fresh perforation of the left eye without foreign body; a forgotten injury of the right eye (proved to harbor a small steel splinter). A magnet extraction was performed by the anterior route on the right eye. The left eye was atropinized and watched for several days after which a linear cataract extraction was performed.

ROENTGENOGRAPHY AND LOCALIZATION

With the clinical examination completed one proceeds to x-ray examination and localization. Accurate localization is the *sine qua non* for the proper management of intraocular foreign bodies. It is best to look up a roentgenologist who takes special interest in foreign body localization. It is good policy for the ophthalmologist to be thoroughly familiar with x-ray foreign body localization. He should be

able to supervise the localization and he should be able to suggest variations in the technique so as to determine whether a fragment is in or just outside the eyeball. Glass (unless containing lead) wood and many other substances are not opaque to x rays. Metallic and stone splinters are x ray opaque. But a minute foreign body can be overlooked. Sometimes artefact shadows are produced by imperfect screens. Because of this it has been our practice to advise first qualitative study by (a) stereo-x ray in posteroanterior view with patient's chin and nose resting on the x ray cassette (b) lateral stereo of the affected eye, (c) skeleton free (soft tissue) technique of Vogt (28-29) for minute fragments in the anterior segment (see Figs. 1-2). The latter is performed by pressing the corner edge of a dental film into the inner canthus and shooting across from the temporal side with the central x ray beam (soft ray). This can be done with the eye looking successively in various directions namely up straight ahead down abducted and adducted as necessary. This exposes all portions of the anterior segment. The eyelids may be pulled out of the way by adhesive strips. A small metal marker attached to the upper and lower limbus at 12 and 6 o'clock helps orientation. Proptosis produced by injecting retrobulbally 2 to 4 cubic centimeters of 2 per cent procaine aids in exposing more of the globe to this skeleton free soft tissue technique. Thus, some substances such as glass or minute metal splinters, which would be obscured by bone shadows and would not show up by the usual technique, become visible by Vogt's method.

Fig. 2. Vogt's skeleton free x ray technique for localization of foreign bodies in the anterior segment of the globe. Plate tube distance 30 inches equals 75 centimeters.

Localization is readily performed by Comberg's method (2-12). This method is simple and accurate when properly applied. It is foolproof for it indicates automatically voluntary or involuntary rotation of the eyeball away from the desired position.

A drop of 0.5 per cent pontocaine is instilled in the conjunctival sac.

A contact lens with 4 lead markers on the limbal sclera is inserted beneath the eyelids so that the raised portion fits over the cornea. The lens is rotated so that the lead markers are at, or nearly at the 3, 6, 9 and 12 o'clock meridians.

First a posteroanterior exposure is made with the patient in prone position (chin and nose resting on cassette to throw the petrous pyramid shadow below the orbit) (Figs. 4-6). The patient looks straight ahead so as to see a reflection of his uninjured eye in the cassette or in a small pocket mirror lying on the cassette before the uninjured eye (Fig. 4a). The central ray (perpendicular to the plate) is aligned with the anteroposterior (visual) axis of the globe. In the presence of strabismus a thin

Fig 6 X-ray localization posteroanterior view (chiasmose position petrous pyramid projected below orbit). Contact lens with lead markers in position. Foreign body is shown by arrow. c is corneal center located by drawing diagonals between markers. Line ab drawn through foreign body and corneal center makes angle ϕ with horizontal orbit line.

Fig 7 X-ray localization lateral exposure. Glass localizing contact lens with lead markers resting on globe. Arrow marks foreign body. Measurements along line cd gives distance of particle behind limbus. Correction factor due to x-ray distortion in Figures 6 and 7 is 10 per cent.

cover glass mounted on a black cardboard triangular wedge is used as an angle mirror to reflect a pocket flash light into the noninjured left fixating eye (Fig 3). The light is held so that the visual axis of the injured right eye is perpendicular to the x-ray plate. The central ray must pass coaxially with the visual line of the injured eye. If one-eyed the patient is instructed to look at the reflection of his eye in the polished cassette surface. If this is not possible due to low visual acuity the angled cardboard mirror and flash light are employed before the only eye. Then a lateral exposure is made with the patient lying on the affected side and looking straight ahead at a mark on the opposite wall. The central ray should pass through the limbal plane bisecting the cornea (Figs. 5-7).

The measurements taken from the posteroanterior and lateral views are corrected for distortion by reducing them by 10 per cent. They are then plotted on Comberg's localization chart (Fig 8). In the posteroanterior view (Fig 6) the lead dot shadows are connected diagonally by lines scratched on the x-ray plate to give the center of the cornea. A line, ab drawn through the foreign body and the corneal center c makes angle ϕ with a line

drawn parallel with the roofs of both orbits. The angle is measured with a protractor and transferred to the localization chart (Fig 8)—and is shown to correspond with the 120 degree meridian. The distance from foreign body to visual axis on x-ray plate (Fig 6) corrected for x-ray distortion by 10 per cent is plotted on this circular front view.

From the lateral exposure (Fig 7) one determines the distance of the foreign body from the limbal plane along the line, cd . The anterior and posterior limits, 13.8 millimeters and 16.6 millimeters respectively are plotted on the meridional section of the eye through the 120 degree meridian. The radial distance—foreign body to posteroanterior axis—is taken from (Fig 6) as plotted on (Fig 8a) and is again plotted on (Fig 8b). This corresponds with its position in the upper temporal quadrant of the posterior vitreous. One can readily realize that a movement of the globe would be shown by a corresponding change in position of the localizing shell. (Figs. 6 and 7 show exposures with a glass contact lens.)

There are several objections to the Comberg contact lens. It does not always lie centered on the cornea and being made of glass can break on falling.

cover glass mounted on a black cardboard triangular wedge is used as an angle mirror to reflect a pocket flash light into the noninjured left fixating eye (Fig. 3). The light is held so that the visual axis of the injured right eye is perpendicular to the x-ray plate. The central ray must pass coaxially with the visual line of the injured eye. If one-eyed the patient is instructed to look at the reflection of his eye in the polished cassette surface. If this is not possible due to low visual acuity the angled cardboard mirror and flash light are employed before the only eye. Then a lateral exposure is made with the patient lying on the affected side and looking straight ahead at a mark on the opposite wall. The central ray should pass through the limbal plane bisecting the cornea (Figs. 5-7).

The measurements taken from the posteroanterior and lateral views are corrected for distortion by reducing them by 10 per cent. They are then plotted on Comberg's localization chart (Fig. 8). In the posteroanterior view (Fig. 6) the lead dot shadows are connected diagonally by lines scratched on the x-ray plate to give the center of the cornea. A line ab drawn through the foreign body and the corneal center c makes angle ϕ with a line

drawn parallel with the roofs of both orbits. The angle is measured with a protractor and transferred to the localization chart (Fig. 8)—and is shown to correspond with the 120 degree meridian. The distance from foreign body to visual axis on x-ray plate (Fig. 6) corrected for x-ray distortion by 10 per cent is plotted on this circular front view.

From the lateral exposure (Fig. 7) one determines the distance of the foreign body from the limbal plane along the line, cd . The anterior and posterior limits, 13.8 millimeters and 16.6 millimeters respectively are plotted on the meridional section of the eye through the 120 degree meridian. The radial distance—foreign body to posteroanterior axis—is taken from (Fig. 6) as plotted on (Fig. 8a) and is again plotted on (Fig. 8b). This corresponds with its position in the upper temporal quadrant of the posterior vitreous. One can readily realize that a movement of the globe would be shown by a corresponding change in position of the localizing shell (Figs. 6 and 7 show exposures with a glass contact lens.)

There are several objections to the Comberg contact lens. It does not always lie centered on the cornea and being made of glass can break on falling.

be done by such methods. Nor are such tests conclusive. The magnet should be applied only in the operating room and then only after x ray localization. The sideroscope was in use in the latter part of the 19th century to determine the magnetic character of foreign bodies. It was unreliable and fell into disuse.

Since 1943 I found the Berman locator especially valuable in determining whether an intraocular foreign body is magnetic or nonmagnetic. It has been useful in locating and pinpointing the spot on the sclera closest to the magnetic fragment. It has served as a check on x ray localization (which is usually correct and occasionally faulty). It has made possible the determination as to whether the fragment has actually moved after magnet application. It has helped me to decide whether the giant magnet or the hand magnet was necessary for extraction of a foreign body. It has served as a psychological comfort throughout the operative procedure. It was first used by Moorhead at Pearl Harbor in 1941. Minsky published the first recorded application of the locator for the transscleral removal of an intraocular foreign body. So far it has not aided in localizing small nonmagnetic fragments.

JUDGMENT AS TO PROCEDURE

Having determined the character and having localized the foreign body, having determined the absence or presence and extent of infection, having arrived at some conclusions as to the amount of ocular trauma and having come to the conclusion that some measure of vision can be saved, one asks himself which foreign bodies should be removed and which might best be left undisturbed?

Chemically inert substances such as glass and stainless steel do not cause ocular irritation as a rule. Aluminum is also well tolerated. On the other hand, brass, copper, zinc and their alloys, iron and steel produce ocular inflammation and deterioration. One must use careful considerate judgment in deciding on operative interference.

Prompt removal of an intraocular foreign body before it sets up too much irritation or infection and before it becomes surrounded by exudate is essential. It is wise to attempt the removal of all irritating nonmagnetic foreign

bodies, if one can avoid excessive mutilation of the globe in doing so. Prompt and early surgery followed by a well considered plan of procedure should be the rule. The surgeon with all facts at hand decides whether operative interference or conservative treatment is to be followed. Should surgery seriously threaten the integrity of the eyeball and prove to be mutilating or destructive, then one must realize that nothing is to be gained by performing an operation.

COMBATING INFECTION—PROPHYLAXIS

Every early foreign body case, when first seen, must be considered as potentially infected. To combat such infection and before any organism can be isolated, the surgeon must rely on prophylactic measures. Since the days of Wagner Jauregg's malaria treatment of syphilis, ophthalmologists have found that foreign protein therapy in the form of 15 to 30 million typhoid bacilli antigen intravenously or 10 cubic centimeters of boiled milk intravitreally are helpful in controlling intraocular inflammation. On admission 1500 units of antitetanic serum is given. Penicillin—100,000 units—is given intramuscularly as an initial dose and is repeated in 50,000 unit doses every 3 hours for 4 to 6 days. We have also found subconjunctival injection of 500 units of penicillin dissolved in 0.5 cubic centimeter normal saline to be helpful.

Sulfadiazine has been especially valuable in our experience in combating infection. Six grams are given during the first 24 hours beginning with a 2 gram dose. Four grams are then given daily in divided doses for another 48 hours. Thereafter 2 grams are given every 24 hours for 5 days. A blood level of 8 to 10 milligrams is desirable. The urine must be watched for sulf crystals. The blood must be watched for leukopenia and anemia.

PREOPERATIVE CARE

As preparation for local anesthesia, pentobarbital 0.1 gram is given 1 hour before operation. The skin is scrubbed with soap, irrigated and painted with 3/4 per cent tincture of iodine or merthiolate.

Local anesthesia is performed in the following manner:

Fig. 9.

Fig. 9. Modified Comberg localizing shell made of plastic or glass. It may be anchored to episclera at 3 suture holes.

Fig. 11.

1. Pontocaine hydrochloride 0.5 per cent is instilled topically 3 drops at 1 minute intervals.

2. Procaine 2 per cent with 1:30,000 epinephrine is injected into the lateral canthus subconjunctivally and into the superior rectus tendon.

3. Akinesia is performed by injecting 5 cubic centimeters of 2 per cent procaine, containing 1 minim of 1:1000 epinephrine 10 to 15 millimeters anterior to the incisura intertragica (ear notch).

4. Retrobulbar injection consists of 0.5 cubic centimeter solution, containing cocaine hydrochloride 1 per cent, procaine 2 per cent, epinephrine 1:30,000.¹

CORNEAL FOREIGN BODIES

Superficial foreign bodies may be wiped off with a moistened cotton applicator after topical anesthesia. Imbedded particles are dislodged with a sharp spud used to pry up the edge of the fragment. Multiple imbedded foreign bodies are readily removed with the 1 millimeter curet.

The narrow beam of the slit lamp microscope is invaluable in ascertaining the depth of a corneal foreign body. It readily affords information as to whether a particle is wholly intracorneal or projects into the anterior chamber. Metallic shivers or wooden splinters between the corneal lamellae are removed by dissecting down on them and then prying them

¹To prepare procaine 2% with 1:30,000 epinephrine, add 1 minim of 1:1000 epinephrine solution to c.c. of 2% procaine solution.

up with a cataract knife. When somewhat dislodged the splinter is grasped with the author's corneal splinter forceps (22) (Fig. 10). This forceps has fine rasped teeth which point backward and provide an excellent hold. Thorns and wood splinters are likely to cause keratitis if removed incompletely. On the other hand small glass spicules or coal particles or powder particles if wholly intracorneal may be left undisturbed since they rarely irritate.

The more troublesome corneal foreign bodies are the ones penetrating to or into the anterior chamber. There is always danger of pushing them into the chamber; also the hazard of producing traumatic cataract if the projecting fragment strikes the lens capsule.

Penetrating corneal foreign bodies in the pupillary zone are best removed by the method suggested by Kuhnt many years ago (Fig. 11). Pilocarpine is used to contract the pupil. A narrow keratome (4 mm. wide) such as that of Agnew or of Castroviejo is introduced through the cornea and the point anchored on the other side. The keratome blade thus lies beneath the foreign body. One now dissects the corneal layers down to the foreign body and removes the fragment with the splinter forceps. The keratome is now withdrawn and the pupil is dilated with atropine. The anterior chamber is restored with normal saline to avoid anterior iris synechia.

A penetrating splinter in the periphery is removed after making a corneal flap inserting 1 or 2 interrupted sutures (Fig. 12). The flap is lifted and the foreign body is removed with

Fig. 2.

Fig. 12. Limbal incision and preplaced sutures for removing peripheral placed penetrating corneal splinter.

Fig. 3. Second step in removal of splinter from everted cornea with forceps.

Fig. 13.

Fig. 14.

Fig. 14. a, Use of blunt iris hook to dislodge fragment wedged in chamber angle. Final removal with forceps. b, Forward incision in cornea permitting access into chamber angle.

forceps from within (Fig. 13). It may be necessary to pry the splinter loose with a knife needle.

Another method for removing deep corneal foreign bodies is to make pressure from inside with a small Reverdin needle (inserted through a keratome incision) against the posterior surface of the cornea while cutting down onto the foreign body (Fig. 15).

FOREIGN BODIES IN THE ANTERIOR CHAMBER

Magnetic particles in the anterior chamber rarely require the insertion of an instrument into the globe, except for toilet of the wound. On the other hand, the nonmagnetic fragment must depend on special forceps, a blunt iris hook, and an Elschnig spatula for its removal. Small particles of glass, coal, inert solids, and rootless lashes do not as a rule require surgery. Copper and brass must be removed.

Fig. 15. Use of Reverdin needle through keratome incision to press foreign body backward through cornea while extraction is attempted from without.

It has been our practice to use the Berman locator in every case, and on occasion we found an intraocular foreign body to be magnetic, when the history suggested otherwise. The penetrating corneal foreign body is at times pushed into the anterior chamber and then it is obviously handled as such.

For the operation one should have at hand the usual iridectomy instruments, plus serrated curved anterior chamber clot forceps, Arruga's capsule forceps, the author's corneal splinter forceps, Tyrrel's blunt iris hook, Elschnig's cycloanalysis spatula, and an anterior chamber irrigator. It should be a rule to fill the anterior chamber with normal saline at the end of the operation. Hyphema should be allowed to absorb or must be irrigated away before removal can be attempted.

Nonmagnetic foreign bodies not enmeshed in iris tissue are readily grasped and removed with one of the above special forceps through a properly placed keratotomy. It is best to avoid the wound of entry unless it is large. The corneal incision should be posterior to the foreign body so that the rear wound lip will not interfere with instrumentation. The particle should be grasped so that it will not dart away. The lens capsule must be avoided. After removal of the fragment, any iris prolapse that may be present is replaced; the chamber is then restored with saline and in most cases it is advisable to close the incision with atraumatic silk sutures. This prevents postoperative iris prolapse. No atropine is instilled at this time. A binocular occlusive dressing is applied. After 3 or 4 days, a per

cent atropine is instilled. Both eyes are kept closed for 1 week if the incision is longer than 6 millimeters.

Anterior chamber foreign bodies of long standing either adherent or enmeshed in iris tissue may at times be teased loose. They usually require an iridectomy. Only the smallest amount of iris tissue should be sacrificed.

ANTERIOR CHAMBER ANGLE

Nonmagnetic particles lodged in the chamber angle present a special problem. Most of them are found in the lower angle recess due to gravity. They are usually wedged between iris and cornea and are often covered by exudate. They may be readily seen by gonioscopy. Removal may be accomplished by a method long in use. A limbal incision is made several millimeters to the side of the particle (Fig. 14a). The fragment is pried loose with a blunt iris hook and is then removed with forceps. The incision is then closed with silk sutures and the anterior chamber is reestablished with normal saline.

Desmarres in 1874, Goulden in 1920 and Lancaster later described another good approach to particles lodged in the anterior chamber angle. An incision is made from within forward across the cornea from 5 to 7 o'clock with a narrow Graefe cataract knife (Fig. 14b). This permits one to pry the foreign body loose with the blunt hook and then to reach in with forceps and remove it. The chamber is restored and the corneal wound is closed with one or two interrupted sutures. Both of the above methods have been tried several times and found satisfactory by the writer.

It may at times be necessary to incise the angle from without (*ab externo*—according to the method of Gayet). Or one can use Meller's method of making a hinged trephine button over the site of the foreign body. Here one must be certain not to have a corneal shelf overlying the fragment in the chamber angle.

IRIS

Nonmagnetic particles lodged in iris tissue at times be freed with forceps inserted through a keratotomy. However when it is only enmeshed or when the iris is excessively automatized in removing the splinter I have

Fig. 16. Method of using author's self-closing vitreous foreign body forceps under ophthalmoscopic control.

found it best to excise a small portion of iris with the foreign body.

POSTERIOR AQUEOUS CHAMBER

To remove foreign bodies from behind the iris just to the side of the lens equator one must have extremely accurate x ray localization with contact lens or limbus marker. A Gayet incision is made subconjunctivally (beneath a previously dissected flap) with Lunds gaard's knife. A McLean corneoscleral suture is then placed and the incision is completed *ab externo* into the chamber angle. A drop of adrenalin 1:100 and a drop of thrombin solution are placed on the iris root to prevent and arrest hemorrhage. Iridodialysis at the root is accomplished by holding the iris up and cutting it at its attachment with pointed scissors under Beebe loupe magnification. The iris is now held aside while the corneal flap is lifted by the assistant. The surgeon reaches in with forceps, grasps the foreign body and removes it. The fragment if present for any length of time may be enmeshed in exudate. One must be extremely careful to avoid lens injury. The incision is closed with the above mentioned suture. A thin strand of iris stroma may be incarcerated in the wound just before closure if the iridodialysis is longer than 3 millimeters. The conjunctival flap may be replaced and held with 2 interrupted silk sutures.

FOREIGN BODIES IN THE LENS

Nonmagnetic foreign bodies are sometimes tolerated by the lens for long periods of time because of its slow metabolism. They may thus be carried along until the lens becomes completely cataractous. For removal of lenticular foreign bodies the pupil must be dilated maximally. Magnetic splinters are readily dislodged with Haab's giant magnet from either partly or wholly cataractous lenses.

To remove visible nonmagnetic splinters from the lens Donovan in 1925 suggested a unique method. A small keratotomy is made and a short beveled 19 gauge hypodermic needle mounted on a Luer syringe is inserted into the lens up to the foreign body. The plunger is pulled on to grasp and hold the foreign particle by suction. Donovan has reported successful extraction of several lenticular foreign bodies by this method.

If the fragment lies just beneath the anterior capsule it may be grasped with a toothed capsule forceps.

The customary practice with foreign bodies in the lens (without irritation of the eye) is to await complete maturity of the cataract. Combined intracapsular extraction is then attempted. In adults under 40 the Pagenstecher technique (of holding a Weber loop or broad spatula just behind the superior lens equator while counter pressure is made at the lower limbus) is employed. Vitreous loss is kept at a minimum by tying previously inserted corneo-scleral sutures. In patients past 40 years of age one tries to remove the lens in capsule using Arruga's forceps or the enucleator. Rupture of the capsule with escape of the foreign body can present a serious complication. If it is visible one can grasp it with forceps. If it is not seen readily then one applies the scleral transilluminator gently to the globe in an attempt to see the foreign body shadow. The cataractous nucleus is expressed. Irrigation under Beebe loupe control is resorted to to float the foreign body into view.

NONMAGNETIC FOREIGN BODY IN CORPUS CILIARIS OR CHORIOID

Accurate localization is essential. A ring marker sown to the episclera is helpful. The conjunctiva is incised several millimeters be-

hind the localized spot and the sclera is bared over this area. The exact spot of localization is marked with gentian violet. A meridional incision is made through the sclera by gradual dissection attempting to come down to the foreign body. The lips of the sclera are held aside by silk sutures (according to Mendoza method). The foreign particle may appear in the uvea herniating into the incision if localization and dissection is accurate. Transillumination (with Lancaster's or Lange's instrument) applied to the opposite side of the globe is helpful. To avoid hemorrhage epinephrine 1:100 is dropped onto the scleral incision with thrombin solution to aid clotting. If the foreign particle lies a little deeper than the ciliary body is incised radially. The particle is seized with forceps when it comes into view. If one waits a minute or two it will at times present itself in the wound and can be removed. Protrusion of ciliary body is excised and the aforementioned Mendoza suture is tied closing the incision. The conjunctiva is closed with running suture. The same technique is followed for particles in the choroid except that the site of incision in the sclera is surrounded with 6 surface coagulations. If the particle is magnetic and near the pars plana of the ciliary body one can use the technique suggested by Verhoeff in 1932 and by Barbour and Fraclik in 1941.

FOREIGN BODIES IN THE VITREOUS CHAMBER

For many years, eyes harboring copper or its alloys in the vitreous were given up to enucleation. Now newer techniques and instruments can save some of these cases. Several methods can be used. The choice of method depends on the location of the particle, on its visibility with the ophthalmoscope and on the cloudiness or bloodiness of the vitreous.

Method 1 for vitreous. Direct vision or ophthalmoscope. In a case with clear lens in vitreous and foreign body visible with ophthalmoscope without undue rotation of the eyeball. The sclera near the foreign body is bared. The site of incision is marked with gentian violet and surrounded by 6 to 8 surface coagulations. A 4 to 8 millimeter long incision is made in the sclera in the shape of capital I or T (with the

long arm of the letter meridional) The length of the incision is governed by the size and shape of the fragment The uvea is exposed while the sclera is held aside with one or two Mendoza sutures The uvea is incised with the cutting current of the diathermy The particle may be seen glistening in the incision and is extracted with forceps and the sclera immediately closed with the above mentioned sutures If the particle is not readily seen in the incision one views it with the ophthalmoscope and extracts it with the author's self closing vitreous chamber (23-24) forceps introduced into the incision The wound is closed as above. It may be touched with trichloroacetic acid or 95 per cent phenol (18) The conjunctival incision is then sutured

Vitreous Method 2 Ophthalmic endoscope
The ophthalmic endoscope was devised in 1934 (25) and demonstrated that Spring in non luminous form at the Section of Ophthalmology of the American Medical Association In the Fall of 1934 (26) the self luminous model was demonstrated at the Academy of Ophthalmology and Otolaryngology I have used it successfully in 5 cases It has been used with success by Spaeth and others.

The endoscope consists of (1) a light carrier with a miniature lamp (2) a special inverted Galilean telescope 2.5 millimeters in diameter and (3) a small tubular forceps. These are held together in one plane by a metal sheath There is an adjustable sleeve which can be preset for depth of entry of the forceps into the vitreous. The operative end of the instrument has a stop to prevent its being thrust into the vitreous chamber bodily There is an electric connection which supplies current for the miniature lamp from a battery. The cross section of the operating end is 2.5 by 6.5 millimeters. The telescope affords a field of view 60 degrees in diameter Thus at 10 millimeters distance the field is 10 millimeters in diameter at 15 millimeters distance it is 15 millimeters in diameter Thus, two thirds or more of the interior can be covered by moderate tilting of the instrument shaft. Particles at 15 millimeters distance from the telescope end are magnified two diameters and become larger as they near the telescope The inverted Galilean system permits everything to be in

Fig 17 Method of holding ophthalmic endoscope during operation. Surgeon's left hand holds and steadies the instrument body. The right thumb and index finger actuate the grasping forceps, *H* whose blades, *F* are seen just beyond the telescope, *T*, and miniature lamp, *L*. *S* Adjustable sheath *C* electric battery connection, *E* eyepiece

focus except that the objects appear smaller as the distance from the telescope lens increases This instrument should be used only in clear vitreous The forceps used are shaped so that some may grasp a shot while another is used for an irregular shaped splinter They are either self-closing or manual closing

It is of extreme importance for the surgeon who proposes to use this instrument to become thoroughly familiar with its application by working in a small light proof pill box (1 inch in diameter—about the size of the globe) The surgeon must learn to overcome the handicap of working with a monocular instrument. He must learn to hold it and handle it properly He must learn to orient himself with the instrument at all times. After mastering removal of small objects from the pill box one advances to practice with pig's eyes.

STERILIZATION OF OPHTHALMIC ENDSCOPE

The instrument is washed with green soap rinsed in distilled water and sterilized by immersion for 20 minutes in 0.1 per cent mercury oxy cyanide solution or 0.03 per cent mercuric phenyl nitrate It is rinsed in sterile water and wiped dry Alcohol or heat sterilization or various chemicals except the ones advised will damage the lens cement and the fine electric insulation and will ruin the instrument

When proposing to use the endoscope one begins with an accurate x ray localization and a definite plan of operation. The approach may be between any of the recti muscles or beneath the superior or inferior rectus after they have been cut at their insertion to the globe. The lateral and medial rectus regions are avoided to prevent injury to the long ciliary arteries. The selected site for scleral incision is plotted with gentian violet and surrounded by surface diathermy coagulations or partly penetrating applications of the Kronfeld diathermy needle. This measure is for the prevention of retinal detachment. The incision is made 7 millimeters long in the meridional direction just down to the choroid. Scleral sutures are inserted in the incisional margins to hold them apart and the ends of the incision are cut at right angles for 1 millimeter on each side and on both ends (so that the incision appears I shaped). Epinephrine 1 per cent solution and thrombin are applied to the choroid surface and after 30 seconds wait the choroid and retina are incised with diathermy or with scissors or with a shallow thrust of a cataract knife. The lips of the wound are held apart with sutures by the assistant and the endoscope is inserted just to the opening with the closed miniature forceps about 5 millimeters in front of the telescope and slightly to one side. The surgeon looks through the eyepiece of the illuminated instrument which is connected to an electric battery with preset rheostat. The assistant watches to see that the body of the instrument is not shoved or pushed into the globe. The surgeon sights the foreign body and grasps it with the forceps. The forceps is closed and pulled up to the telescope slowly and the entire instrument is withdrawn. During the procedure one assistant keeps the wound flaps against the sheath of the endoscope with his sutures so as to avoid loss of vitreous. On removal of the instrument he closes the incision and ties the scleral sutures. The conjunctiva is closed with running suture. Of 5 patients operated upon, one has 20/30 vision, another has 20/100 vision, a third case can count fingers. The fourth patient has a blind soft eye. The fifth case done in October 1946 has 10/100 vision with a partial traumatic cataract. This is a major procedure and

the surgeon who uses this instrument should play with it for several weeks before he inserts it into an eye.

Vitreous Method 3. Transillumination. By this method one exposes the sclera as above for transscleral approach. One or two small trans illuminators are placed on the opposite side of the globe to the incision, thus illuminating the vitreous. The foreign body is outlined against the illuminated interior between the lips of the scleral incision. The foreign body is visualized and grasped with small serrated forceps. The incision is closed as in the first two methods. The sclera is also diathermized about the incision to seal off the retinal hole and prevent detachment. I have used this method in 3 instances and am favorably impressed by it. Schutz and Lindner have applied this method.

Vitreous Method 4. Biplane fluoroscope. Cross has found the biplane fluoroscope useful in the removal of shot from the eye. Smaller objects do not cast sufficient shadow to be visible with the fluoroscope. He inserts a cross action wire forceps into the vitreous and is guided in his movements by the fluoroscopist. In the hands of Cross with the aid of his expert fluoroscopist the method has proved successful in several cases. I have had no personal experience with this technique because of lack of a biplane fluoroscope.

Optic nerve. Foreign bodies in the head of the optic nerve can probably be removed with the ophthalmic endoscope. The damage to the nerve head with subsequent cicatrization would probably result in a blind eye. Although removal of magnetic fragments from the nerve head is sometimes followed by moderately useful vision.

Nonmagnetic scleral foreign bodies. Scleral foreign bodies generally do little damage unless they project from either side of the sclera. They can be readily localized and dissected out and sometimes pried loose. If one is in doubt about the location of the foreign body the sclera can readily be palpated with a probe or the end of a muscle hook. The site of the hard particle can be definitely felt.

Orbital foreign bodies can usually be left alone unless because of location or size they make pressure on vital structures or cause dis-

comfort and pain. They do not come within the scope of this paper.

Postoperative treatment The postoperative management consists of

1 *Antibiotics* Sulfadiazine has proved the most successful agent in my experience for controlling infection. In fresh injuries 30 grains is given on admission and is followed by 15 grains every 4 hours for 1 or 2 days. The dosage is then reduced to 15 grains every 6 hours for another 48 hours. Thereafter 15 grains are given 3 times daily for 3 to 4 days. Sodium bicarbonate in the amount of 10 grains is given with each dose and a liter of water is consumed daily. The urine is watched for crystals. The blood level of sulfadiazine is kept between 8 and 10 milligrams. The blood count is also watched for reduction in red and white blood cells and their differentiation.

Penicillin may be given intramuscularly. The first dose is 100,000 units in 5 cubic centimeters of $\frac{1}{4}$ per cent novocain. Thereafter 25 to 50 thousand units are given intramuscularly every 3 hours for 3 to 4 days.

2 *Foreign protein therapy*—Tetanus anti-toxin is given subcutaneously as a specific for the prevention of lockjaw in fresh injuries. Boiled milk in 10 cubic centimeters amount for men and 8 cubic centimeters dose for women and appropriate smaller dosage for children is given intramuscularly on admission to fresh injuries and every third day for 3 doses if indicated.

Typhoid A antigen is given intravenously instead of the intramuscular milk. The first dose is 15 to 20 million. It is increased by 15 to 20 million every third or fourth day as necessary. A reaction is desirable. Old people do not tolerate this therapy well.

3 *Atropine* is used postoperatively unless contraindicated by a rise in tension. Its application is delayed for 3 days in anterior chamber cases. (It is not used preoperatively in anterior chamber cases.)

4 *Daily dressings* are done for traumatic cataract and postoperative intis for atropine instillation. Other intraocular cases are dressed every other day. Both eyes are usually kept closed for 1 week. Cases of retinal detachment or threatened detachment have both eyes kept closed for 2 to 4 weeks.

5 *Position in bed* Patients with wounds of the cornea are required to lie flat in bed for 48 hours. Scleral wounds or incisions do best when kept flat for one week. Incisions in the lower sclera require several days longer in a flat position.

6 *Diet* Liquid diet is given for 48 hours. Soft diet follows for 4 days. Light general diet is given after 6 days postoperatively.

7 *Bowels* The intestinal tract is kept cleared by mineral oil given for 3 days. Simple enemas are given after 48 hours if necessary.

8 *Sedatives* Codein sulfate in doses of $\frac{1}{4}$ to 1 gram may be given and repeated. Phenobarbital in $\frac{1}{4}$ grain doses is at times used as a sedative.

GENERAL RULES IN NONMAGNETIC INTRAOCULAR FOREIGN BODY CASES

1 Make a careful examination and take a complete history. Use every modern device for arriving at a complete diagnosis.

2 Get an idea as to the extent of trauma to the various structures and as to the impairment of function.

3 Assay the probability and extent of infection. Consider each case as potentially infected. Take prophylactic and therapeutic measures for its control.

4 Make an x ray examination in each case with varied types of exposure and position. Stereoscopic x ray films are valuable. Accuracy in localization is paramount.

5 Avoid removal of chemically inert foreign bodies unless they do harm because of size or mechanical irritation.

6 Avoid mutilating surgery and avoid groping in the vitreous. They lead to destruction of vision and of the globe.

7 Suspect and treat immediately all retinal detachments. Take precautionary preventive measures as outlined above.

8 Remove intraocular foreign bodies promptly to prevent their becoming enmeshed in exudate and organized scar tissue and also to prevent the damage that results from prolonged stay in the eyeball.

9 Multiple intraocular foreign bodies make conservative therapy a consideration of the first importance.

When proposing to use the endoscope one begins with an accurate x ray localization and a definite plan of operation. The approach may be between any of the recti muscles or beneath the superior or inferior rectus after they have been cut at their insertion to the globe. The lateral and medial rectus regions are avoided to prevent injury to the long ciliary arteries. The selected site for scleral incision is plotted with gentian violet and surrounded by surface diathermy coagulations or partly penetrating applications of the Kronfeld diathermy needle. This measure is for the prevention of retinal detachment. The incision is made 7 millimeters long in the meridional direction just down to the choroid. Scleral sutures are inserted in the incisional margins to hold them apart and the ends of the incision are cut at right angles for 1 millimeter on each side and on both ends (so that the incision appears I shaped). Epinephrine 1 per cent solution and thrombin are applied to the choroid surface and after 30 seconds wait the choroid and retina are incised with diathermy or with scissors or with a shallow thrust of a cataract knife. The lips of the wound are held apart with sutures by the assistant and the endoscope is inserted just to the opening with the closed miniature forceps about 5 millimeters in front of the telescope and slightly to one side. The surgeon looks through the eyepiece of the illuminated instrument which is connected to an electric battery with preset rheostat. The assistant watches to see that the body of the instrument is not shoved or pushed into the globe. The surgeon sights the foreign body and grasps it with the forceps. The forceps is closed and pulled up to the telescope slowly and the entire instrument is withdrawn. During the procedure one assistant keeps the wound flaps against the sheath of the endoscope with his sutures so as to avoid loss of vitreous. On removal of the instrument he closes the incision and ties the scleral sutures. The conjunctiva is closed with running suture. Of 5 patients operated upon, one has 20/30 vision another has 20/100 vision, a third case can count fingers. The fourth patient has a blind soft eye. The fifth case done in October 1946 has 10/100 vision with a partial traumatic cataract. This is a major procedure and

the surgeon who uses this instrument should play with it for several weeks before he inserts it into an eye.

Vitreous Method 3 Transillumination. By this method one exposes the sclera as above for transcleral approach. One or two small transilluminators are placed on the opposite side of the globe to the incision, thus illuminating the vitreous. The foreign body is outlined against the illuminated interior between the lips of the scleral incision. The foreign body is visualized and grasped with small serrated forceps. The incision is closed as in the first two methods. The sclera is also diathermized about the incision to seal off the retinal hole and prevent detachment. I have used this method in 3 instances and am favorably impressed by it. Schmitz and Lindner have applied this method.

Vitreous Method 4 Biplane fluoroscope. Cross has found the biplane fluoroscope useful in the removal of shot from the eye. Smaller objects do not cast sufficient shadow to be visible with the fluoroscope. He inserts a cross action wire forceps into the vitreous and is guided in his movements by the fluoroscopist. In the hands of Cross with the aid of his expert fluoroscopist the method has proved successful in several cases. I have had no personal experience with this technique because of lack of a biplane fluoroscope.

Optic nerve. Foreign bodies in the head of the optic nerve can probably be removed with the ophthalmic endoscope. Although removal of magnetic fragments from the nerve head is sometimes followed by moderately useful vision.

Nonmagnetic scleral foreign bodies. Scleral foreign bodies generally do little damage unless they project from either side of the sclera. They can be readily localized and dissected out and sometimes pried loose. If one is in doubt about the location of the foreign body the sclera can readily be palpated with a probe or the end of a muscle hook. The site of the hard particle can be definitely felt.

Orbital foreign bodies can usually be left alone unless because of location or size they make pressure on vital structures or cause dis-

VISUAL FIELD DEFECTS DUE TO HEAD INJURIES

JOHN S. McGAVER, M.D. Bryn Mawr, Pennsylvania

THE visual pathways are so extensive that injury to any part of the cranium may result directly or indirectly in defects in the field of vision. These pathways extend from the ganglion cells of the retina by way of the optic nerves, the chiasm, the optic tracts, the lateral geniculate bodies and the optic radiations to the visual cortex in the occipital lobes. The additional cortex and fibers necessary for voluntary and reflex movements, visuopsychic functions and association of one area with various other areas compose a still more complicated and extensive network which involves every portion of the brain.

This paper will consider only the representation of various parts of the retina in the visuosensory cortex of the occipital lobes of the brain. An attempt will be made to summarize our present knowledge and to point out the difficulties in studying this subject. Proof that a given area of the cortex subserves a certain function is difficult as one seldom sees a clean-cut, isolated lesion to correlate with one's clinical findings.

First let us review the anatomy of the visual pathways. The nerve fibers from the temporal halves of each retina pass backward in the temporal portion of the optic nerve; they do not cross in the optic chiasm. Fibers from the nasal halves of the retina pass backward in the nasal portion of the optic nerve but decussate at the chiasm. Fibers from the fixation area or macula form the papillomacular bundle which enters inferotemporally and then assumes a more central position. In the chiasm these fibers lie posteriorly and undergo semidecussation.

Behind the chiasm are the optic tracts, each of which is made up of (1) fibers from the temporal portion of the retina of the same side, (2) fibers from the nasal half of the retina of the opposite side and (3) macular fibers from the temporal half of the same side and from

the nasal half of the opposite side. Thus the macular fibers may be said to form a minor chiasm within the major chiasm. This semidecussation of the central fibers is most important as we shall note again.

The least possible confusion will be had if we look upon the central area of the field as having the same characteristics as the peripheral field. The optic tracts remain condensed throughout their course and end in the lateral geniculate bodies.

From the geniculate bodies to the occipital cortex we find the optic radiations. The geniculocalcarine fibers lie in the internal capsule behind the sensory fibers and internal to the auditory fibers. Fibers from the upper retinal quadrants (lower portion of the visual fields) lie dorsally while fibers from the lower retinal quadrants (upper fields) lie ventrally. In the anatomical space between these lie the macular fibers (the central field). Some of the ventral fibers detour into the uncus region of the temporal lobe around and over the anterior horn of the lateral ventricle before bending backward along the lower aspect of the ventricle to end in the anterior portion of the lower calcarine cortex. These fibers correspond to the temporal crescents of the field. The majority of the fibers in the optic radiations pass directly to the calcarine cortex.

Observers have diverse opinions regarding the representation of the fixation area or macula in the cerebral cortex. A review of their reasons would serve no useful purpose here.

The visual cortex occupies part of the medial surface of each occipital lobe and posteriorly the visual area extends a little onto the lateral surfaces. The visual area extends from the tip of each lobe where the fixation area is represented forward to the splenium of the corpus callosum at the anterior end of the calcarine fissure where the periphery of the retina is represented. The lingual gyrus lies below and the cuneus above the calcarine fissure. The upper portion of each retina is represented in the area above the calcarine fissure.

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, December 16-20, 1946.

10 Do not overlook foci of infection and other systemic conditions that may delay healing and cause complications.

11 Have a definite well considered plan for each operation

12 Know your surgical instruments thoroughly and be sure that they are in first class working order

13 Be sure of the ophthalmic endoscope before attempting its use. This can only be had after continued and repeated practice so that its operation is automatic. When properly used this instrument may be invaluable in salvaging a potentially lost eye due to a retained nonmagnetic foreign body

14. Scleral and corneal incisions and wounds heal faster and better when properly approximated by sutures.

15 The topical application of epinephrine 1:100 and thromboplastin or thrombin will often prevent destructive hemorrhage

16 Enucleation is sanctioned only when the globe is collapsed and extensive vitreous loss has taken place and light perception is lost. Do not rush to enucleate when both eyes are injured.

17 Remember the danger of sympathetic ophthalmia. Three weeks is the safe period at the longest to temporize from the time of injury. A decision should be arrived at within 14 to 16 days as to enucleation of a potentially dangerous eye.

The subject was considered from the standpoint of adequate thorough survey of the injured patient including history and every necessary examination to arrive at an accurate diagnosis. Consideration was given to con-

servative treatment for chemically inert foreign bodies. Techniques were outlined for these measures and for simple accurate methods of x ray localization. Operative techniques were described for the removal of nonmagnetic intraocular foreign bodies, from cornea, anterior chamber iris, lens, ciliary body vitreous, choroid and sclera.

tion. We would like to have had more complete neurosurgical notes but we also understand why they are not available.

When the ophthalmologist is plotting and interpreting visual fields, it is essential that he bear in mind the fact that injuries other than the one producing the field defect may affect the results obtained. Lasting of some of these factors may help to illustrate this point.

1. The patient may not understand what is expected of him during the test.

2. Emotional instability and fatigue may affect the result. It is not easy for even a normal person to have his fields checked.

3. Hysteria and malingering may be responsible for part of the defect. One usually thinks of hysteria and malingering as pure or isolated phenomena. A patient who has sustained a genuine injury resulting in partial loss of his visual field may exaggerate this loss of his field because of fear or a desire to obtain a greater disability pension.

4. Paralysis of extraocular muscles may result in apparently defective visual acuity or defects in the visual field which disappear when the head is placed in the proper position. Paralysis of the sixth nerve or conjugate deviation of the eyes are two examples. Here again there may be a true field defect exaggerated by improper position of the patient.

5. Poor response due to involvement of Wernicke's auditory area (areas 41 and 42 of Brodman) may prevent proper responses to vocal instructions.

6. Involvement of the motor speech area of Broca (area 44 of Brodman) may result in poor vocal responses from the patient.

7. The patient may have difficulty in fixing or maintaining fixation of the target because of poor visual acuity, central scotoma, or a hemianopic defect with splitting of the fixation area. Conversely patient may seem to maintain fixation better than he actually does.

8. The visuopsychic areas may also be involved and make it difficult or impossible for the patient to give adequate responses when being tested.

Area 18, the parastriate area, surrounds the visuosensory area (17) in the occipital cortex. A lesion here prevents a patient from recognizing an object even though he sees it.

Area 19, the peristriate area, surrounds area 18. The patient may see (area 17) and recognize (area 18) but be unable to remember or revisualize the characteristics of an object.

Because of the proximity of areas 17, 18, and 19 more than one area may be destroyed by the injury.

9. Lesions in the parietal lobe

Area 39, lying anterior to area 19, in the angular gyrus of the parietal lobe has to do with interpretation of symbols combining recognition and revisualization (which are dealt with separately in areas 18 and 19).

Area 40 deals with mathematical figures and calculations. It is located in the supramarginal gyrus of the parietal lobes.

Areas 39 and 40 are said to be more dominant than areas 18 and 19.

10. Disturbances of higher psychic and association areas may also interfere with proper testing of the visual fields.

Some of the factors listed above are of practical importance and easily demonstrated. Those which deal with psychic and association functions are listed as of theoretical interest as our precise knowledge is too limited for practical clinical application. The opportunity for further study is with us today as never before because of the many service men who have survived a great variety of head injuries. It is to be hoped that Veterans Hospital staffs will follow these patients carefully with repeated neurological, neurosurgical, ophthalmological and finally with postmortem studies. When the injured brain is fixed and studied grossly and microscopically we can find the true extent of the lesions which resulted in visual field changes observed during life. This should settle many disputed points—but will do so only if our clinical notes are accurate and complete.

If this demonstration stimulates others by its inadequacies rather than by its excellence of detail its purpose will have been served.

CASE REPORTS

These cases were collected in conjunction with Dr. J. N. Greear, Jr. now in Washington, D. C. and formerly Chief of Eye Section, Valley Forge General Hospital.

CASE 1. This patient sustained a fracture of the left parietal and occipital bones with multiple depressed fragments of bone, laceration of the dura and

while the lower portions of the retinas are represented below the calcarine fissure. Sectors adjacent to the vertical meridian of the retina are represented along the lips of this fissure, while sectors to the sides of the horizontal meridians are projected in the depths of the fissure. The temporal crescents of the binocular fields are represented in the oral parts of the calcarine fissure.

The cortical area representing the fixation area is quite extensive as compared with the area representing the peripheral portions of the visual fields. This is analogous to the large motor and sensory areas in the parietal cortex representing finger and thumb as compared with the area representing trunk.

It is unfortunate that our methods of studying cerebral localization are so limited. Obviously we cannot induce lesions in human subjects, nor can we obtain subjective responses from animals. Electrical stimulation of the visual cortex of man results in responses less precise and more difficult to interpret than the responses invoked by test objects used in taking visual fields. Electroencephalography has so far shown little promise as a method of studying the visual apparatus. Complete neurological and ophthalmological examinations are our best methods, and plotting of the visual fields the most satisfactory single test.

Four types of lesions in the brain can be correlated with visual field defects. Each of these has its disadvantages and limitations. Vascular lesions have provided valuable information regarding cerebral localization. However individual variations in blood supply are not infrequent. Occlusion of certain cerebral arteries is common, but occlusion of smaller branches supplying small areas of the cortex is not common.

While some tumors produce clean-cut field defects, much depends upon the time of study of an expanding lesion. Infiltrating tumors have indefinite borders. Local or distantly applied pressure from a tumor may result in atrophy, edema, or vascular occlusion in areas remote from the space-taking lesion.

Excision of tumors or of scar tissue allows the neurosurgeon to note the exact area involved. This is our best method of clinical study.

Injuries provide the next best method. One must keep in mind several factors which may affect the interpretation of traumatic lesions. One of these is the element of time as hemorrhage, edema, and contusion produce varying pictures.

Regardless of the lesion studied, post mortem examination with sections of the entire brain is by all odds the most reliable.

Among the factors that render interpretation of visual field defects due to injuries hazy and difficult are these:

- 1 Depressed skull fractures produce effects which are at least partially reversible by elevation of the fragments.

- 2 Foreign bodies may be found at one site, but have traversed important structures in reaching this site. It is therefore most important to know the location of the entire tract of a foreign body.

- 3 Blood vessels may be torn or thrombosed giving the picture of a vascular lesion alone or a combination of vascular, cortical, and radiation fiber injury. Indeed, vascular injury may play a rôle in a high percentage of field defects due to trauma. We may say that it is unimportant to know whether damage to cortical cells is direct or due to loss of blood supply. However the field defect is likely to be larger in a vascular injury. The prognosis is often much better when the blood vessels are only partially or temporarily occluded. It is important to remember that terminal branches of the calcarine and middle cerebral arteries do have anastomoses in the pia before piercing the cortex.

- 4 Edema from any cause may be responsible for transient effects on the visual fields.

- 5 A brain abscess may be a late, unexpected complication of injury and add its effects to the visual field defect.

- 6 The neurosurgeon may not be able to tell how much of the lesion is destructive and how much is due to edema, hemorrhage, or contusion. He is handicapped in observing landmarks and often cannot see the entire extent of the injury because of the small opening in the calvarium through which he operates. The brilliant work of the neurosurgeons in the past war has kept alive many men who would otherwise not have returned to us for examina-

tion. We would like to have had more complete neurosurgical notes but we also understand why they are not available.

When the ophthalmologist is plotting and interpreting visual fields, it is essential that he bear in mind the fact that injuries other than the one producing the field defect may affect the results obtained. Listing of some of these factors may help to illustrate this point.

1 The patient may not understand what is expected of him during the test.

2 Emotional instability and fatigue may affect the result. It is not easy for even a normal person to have his fields checked.

3 Hysteria and malingering may be responsible for part of the defect. One usually thinks of hysteria and malingering as pure or isolated phenomena. A patient who has sustained a genuine injury resulting in partial loss of his visual field may exaggerate this loss of his field because of fear or a desire to obtain a greater disability pension.

4 Paralysis of extraocular muscles may result in apparently defective visual acuity or defects in the visual field which disappear when the head is placed in the proper position. Paralysis of the sixth nerve or conjugate deviation of the eyes are two examples. Here again there may be a true field defect exaggerated by improper position of the patient.

5 Poor response due to involvement of Wernicke's auditory area (areas 41 and 42 of Brodman) may prevent proper responses to vocal instructions.

6 Involvement of the motor speech area of Broca (area 44 of Brodman) may result in poor vocal responses from the patient.

7 The patient may have difficulty in fixing or maintaining fixation of the target because of poor visual acuity, central scotoma, or a hemianopic defect with splitting of the fixation area. Conversely patient may seem to maintain fixation better than he actually does.

8 The visuospsychic areas may also be involved and make it difficult or impossible for the patient to give adequate responses when being tested.

Area 18 the parastriate area, surrounds the visuosensory area (17) in the occipital cortex. A lesion here prevents a patient from recognizing an object even though he sees it.

Area 19 the peristriate area, surrounds area 18. The patient may see (area 17) and recognize (area 18) but be unable to remember or revisualize the characteristics of an object.

Because of the proximity of areas 17, 18 and 19 more than one area may be destroyed by the injury.

9 Lesions in the parietal lobe.

Area 39 lying anterior to area 19 in the angular gyrus of the parietal lobe has to do with interpretation of symbols combining recognition and revisualization (which are dealt with separately in areas 18 and 19).

Area 40 deals with mathematical figures and calculations. It is located in the supramarginal gyrus of the parietal lobes.

Areas 39 and 40 are said to be more dominant than areas 18 and 19.

10 Disturbances of higher psychic and association areas may also interfere with proper testing of the visual fields.

Some of the factors listed above are of practical importance and easily demonstrated. Those which deal with psychic and association functions are listed as of theoretical interest as our precise knowledge is too limited for practical clinical application. The opportunity for further study is with us today as never before because of the many service men who have survived a great variety of head injuries. It is to be hoped that Veterans Hospital staffs will follow these patients carefully with repeated neurological, neurosurgical, ophthalmological and finally with postmortem studies. When the injured brain is fixed and studied grossly and microscopically we can find the true extent of the lesions which resulted in visual field changes observed during life. This should settle many disputed points—but will do so only if our clinical notes are accurate and complete.

If this demonstration stimulates others by its inadequacies rather than by its excellence of detail its purpose will have been served.

CASE REPORTS

These cases were collected in conjunction with Dr J. N. Greear Jr. now in Washington D.C. and formerly Chief of Eye Section Valley Forge General Hospital.

CASE 1 This patient sustained a fracture of the left parietal and occipital bones with multiple depressed fragments of bone laceration of the dura and

while the lower portions of the retinas are represented below the calcarine fissure. Sectors adjacent to the vertical meridian of the retina are represented along the lips of this fissure while sectors to the sides of the horizontal meridians are projected in the depths of the fissure. The temporal crescents of the binocular fields are represented in the oral parts of the calcarine fissure.

The cortical area representing the fixation area is quite extensive as compared with the area representing the peripheral portions of the visual fields. This is analogous to the large motor and sensory areas in the parietal cortex representing finger and thumb as compared with the area representing trunk.

It is unfortunate that our methods of studying cerebral localization are so limited. Obviously we cannot induce lesions in human subjects, nor can we obtain subjective responses from animals. Electrical stimulation of the visual cortex of man results in responses less precise and more difficult to interpret than the responses invoked by test objects used in taking visual fields. Electroencephalography has so far shown little promise as a method of studying the visual apparatus. Complete neurological and ophthalmological examinations are our best methods, and plotting of the visual fields the most satisfactory single test.

Four types of lesions in the brain can be correlated with visual field defects. Each of these has its disadvantages and limitations. Vascular lesions have provided valuable information regarding cerebral localization. However in individual variations in blood supply are not infrequent. Occlusion of certain cerebral arteries is common but occlusion of smaller branches supplying small areas of the cortex is not common.

While some tumors produce clean-cut field defects, much depends upon the time of study of an expanding lesion. Infiltrating tumors have indefinite borders. Local or distantly applied pressure from a tumor may result in atrophy, edema, or vascular occlusion in areas remote from the space-taking lesion.

Excision of tumors or of scar tissue allows the neurosurgeon to note the exact area involved. This is our best method of clinical study.

Injuries provide the next best method. One must keep in mind several factors which may affect the interpretation of traumatic lesions. One of these is the element of time as hemorrhage, edema, and contusion produce varying pictures.

Regardless of the lesion studied, post mortem examination with sections of the entire brain is by all odds the most reliable.

Among the factors that render interpretation of visual field defects due to injuries hazardous or difficult are these

- 1 Depressed skull fractures produce effects which are at least partially reversible by elevation of the fragments.

- 2 Foreign bodies may be found at one site, but have traversed important structures in reaching this site. It is therefore most important to know the location of the entire tract of a foreign body.

- 3 Blood vessels may be torn or thrombosed giving the picture of a vascular lesion alone or a combination of vascular, cortical, and radiation fiber injury. Indeed, vascular injury may play a rôle in a high percentage of field defects due to trauma. We may say that it is unimportant to know whether damage to cortical cells is direct or due to loss of blood supply. However the field defect is likely to be larger in a vascular injury. The prognosis is often much better when the blood vessels are only partially or temporarily occluded. It is important to remember that terminal branches of the calcarine and middle cerebral arteries do have anastomoses in the pua before piercing the cortex.

- 4 Edema from any cause may be responsible for transient effects on the visual fields.

- 5 A brain abscess may be a late, unsuspected complication of injury and add its effects to the visual field defect.

- 6 The neurosurgeon may not be able to tell how much of the lesion is destructive and how much is due to edema, hemorrhage, or contusion. He is handicapped in observing landmarks and often cannot see the entire extent of the injury because of the small opening in the calvarium through which he operates. The brilliant work of the neurosurgeons in the past war has kept alive many men who would otherwise not have returned to us for examina-

On the eighth day after injury a second craniotomy was done evacuating a subdural hematoma which was compressing the left occipital lobe by 1.5 centimeters. When the necrotic tissue of the brain was removed, a defect 3 centimeters deep remained. Then a clot was removed from the right occipital lobe whose cortex was largely liquefied. The neurosurgeon's operative note states, 'There was considerable damage to both occipital lobes thus accounting for the blindness. The damage however did not appear to me to destroy the calcarine area completely and it may be that after edema subsides vision may return, particularly in the upper fields.'

Three weeks after injury the patient had light perception. Vision gradually improved. Eight months later vision was right eye 20/40 J 6 and left eye 20/50 J 1.

Visual fields showed loss of all but the central one degree. The patient can read only one letter at a time, but he says he sees this clearly.

We have definite evidence of severe damage to both occipital lobes and a note that all of the calcarine area did not appear to be destroyed. There must be damage to the anterior portion of the calcarine areas, and undoubtedly to the optic radiations.

In these patients we must be on the lookout for hysteria or exaggeration of the field defect despite the genuine severe injury. That is they must have a large field defect due to injury but for some reason may show too much loss. A medical officer once told me of suspecting a patient with such a field of getting around too well. Under sodium amytal the patient confessed that he had a wider field but because of a personal problem he elected to show this limited field.

So far as we were able to ascertain 2 of our patients actually had this type of field. Similar cases have been described by Gordon Holmes and by Scarlett and Ingham after World War I. McDonald has described bilateral homonymous hemianopia due to bilateral occlusion of the calcarine arteries. A vertical strip of field was retained below the spared fixation area.

CASE 7 This patient showed field defects which are the antithesis of the last one. That is he has bilateral central scotomas with normal peripheral fields.

He was injured by shrapnel sustaining a depressed fracture of the occipital bone with multiple foreign bodies. The next day débridement of the wound was carried out. Three days later vision began to improve and did so for 2 months. Four months after injury the depressed fracture was elevated, pieces of bone and shrapnel were removed from the right occipital lobe. Both occipital lobes were found contused and degenerated, some of the cortex being replaced by xanthochromic scar tissue.

Vision was 20/300 J 0 eccentric in each eye. The peripheral fields were normal. The central fields showed bilateral central scotomas with most of the scotoma to the right of the midline. Injury to the cortex at the tip of both occipital lobes especially the left accounts for the field defect.

Gordon Holmes has shown a variety of homonymous central field defects, both unilateral and bilateral.

SUMMARY

A review of the anatomy of the visual pathways has been given.

The areas of the visual cortex representing all parts of the retina (or of the visual fields) have been pointed out.

An attempt has been made to show the difficulties encountered in studying the visual cortex.

Seven illustrative case reports are given.

It is hoped that Veterans Hospitals will compile extensive data on casualties of this type following through to postmortem examination as this is the only reliable method of determining the many things we do not know about cerebral functions. The opportunity is greater than ever before and we trust shall never be so great again.

brain and an intracerebral clot. Craniotomy was performed 3 days later followed by drainage of cerebrospinal fluid for a period of 4 weeks.

Röntgenogram of the skull showed an oval area of bony dehiscence measuring 5 by 3 centimeters in the posterior portion of the left parietal bone and anterior portion of the left leaf of the occipital bone.

The field defect was right homonymous hemianopsia with sparing of the fixation area and a portion of the right field adjacent to the vertical meridian. Visual acuity was 20/15 Jt in each eye.

The site of injury data obtained at operation, plus the field defect indicate a lesion of the left occipital cortex, probably vascular in type. Sparing of fixation is due to the dual blood supply to the cortex.

CASE 3. This patient sustained a severe compound comminuted fracture of both leaves of the occipital bone, with stellate fractures of both parietal bones. Multiple foreign bodies were seen at a depth of 5 to 6 centimeters in the left parieto-occipital area.

Craniotomy was performed the next day. Debridement left a 6 by 3 centimeter defect in the occipital bone. A hematoma and damaged tissue of the brain were removed. The foreign bodies were not removed from the left occipital lobe.

The patient was apparently blind for a period of 15 days, during which time both pupils reacted to light. He also showed sensory aphasia and generalized hyperreflexia. Bilateral papilledema was present for a considerable length of time before subsiding spontaneously.

Röntgenogram showed a 4 by 8 centimeter defect in the occipital bone more to the left side. Linear fractures radiated in all directions from this defect. Two large foreign bodies were present in the parietal lobe 9 centimeters above the mastoid bone.

The field defect was right homonymous hemianopsia with division or splitting of the fixation area. Visual acuity was right eye 20/70 plus 2 Jts and left eye 20/100 plus 1 Jt. Degenerative changes visible in the nerve heads and maculae, a result of prolonged papilledema account for the decreased acuity.

The information obtained at operation plus the field defect place this lesion in the left occipital cortex and deeper tissues of the brain. The sensory aphasia and hyperreflexia were due to damage to the parietal lobe.

CASE 3. This patient sustained a penetrating wound of the skull and both occipital lobes by a shell fragment which entered the left occipital and came to rest in the right occipital lobe. The foreign body was removed and débridement carried out.

X-ray examination showed a large surgical defect involving the union and upper portion of the occipital bone—with fracture lines radiating into the left parietal bone and to both petrous pyramids.

Visual acuity was right eye ability to count fingers at 1 foot nasally and left eye at 3 feet temporally. There was conjugate deviation of the eyes to the right; pupils reacted to light; fundi were normal.

The field defect was right homonymous hemianopsia plus a small central defect in each field. Dam-

age to the entire left visual cortex and to the tip of the right occipital lobe by the foreign body accounts for the field defect.

CASE 4. This patient was struck by mortar shell fragments, sustaining a compound, comminuted fracture of the occipital bone with depressed fragments driven into right occipital lobe of brain.

Two days after injury craniotomy was done. The tip of the right occipital pole and the calcarine area were destroyed by the fragment of bone. The dura was torn on both sides of the midline. The longitudinal sinus was thrombosed. The patient was unconscious for 11 days. Examination on about the fourteenth day showed complete blindness lasting several more days. Later the patient showed homonymous hemianopsia by the confrontation method. The fundi were normal. Vision was reduced to ability to count fingers.

X-ray examination showed a 4.5 by 6 centimeter defect in the middle of the occipital bone with a stellate fracture extending into the right parietal bone.

The last field examination showed a left homonymous hemianopsia plus loss of part of the right lower quadrants of the field and involvement of both fixation areas. The field defect is explained by damage to the right calcarine area and tip of the right occipital lobe. The left occipital lobe must have been damaged above the calcarine fissure with injury to the tip of the occipital lobe or the central fibers beneath the cortex.

CASE 5. This patient was injured in a plane crash sustaining a compound depressed skull fracture in the midoccipital region. Thirty-six hours later the depressed fracture was elevated. Two fragments just to the right of the midline were found 1.5 centimeters below the dura piercing the longitudinal sinus. A larger portion of the right leaf was pressed outward into proper position. The dura was intact except at the longitudinal sinus. The field defect 4 weeks later was a left homonymous hemianopsia sparing the fixation area. Vision was 20/30 Jt in each eye.

Four months later the field defect was a left homonymous lower quadrantanopsia with sparing of the fixation area. Vision had improved to right eye 20/15 Jt and left eye 20/20 Jt.

Here we know that the right occipital cortex was damaged. The improved fields are explained by recovery from edema or contusion of the cortex adjacent to the destroyed cortex.

CASE 6. This is one of two patients with bilateral homonymous hemianopsia with sparing of the fixation area and retention of good central vision in each eye. This patient was injured by artillery shell fragments, sustaining a compound, depressed fracture of the left leaf of the occipital bone and several foreign bodies in the left frontal lobe of the brain.

On the day of injury the wound was débrided and the longitudinal sinus packed with muscle tissue to arrest bleeding. One week later the patient was completely blind had a bilateral papilledema but his pupils reacted to light.

On the eighth day after injury a craniotomy was done evacuating a subdural hematoma which was pressing the left occipital lobe 1.5 centimeters. When the next incision was made a defect 3 centimeters in diameter was removed. The area was removed from the right hemisphere and was largely liquefied. The patient was operated on 10 days later. There was no damage to both occipital lobes. The patient refused the Holmes test. The damage however appeared to me to be in the calcarine area. It is likely a bit may be that after the operation may return particularly in the upper field.

Three weeks after injury the patient had a correction. An area gradually improved. The left eye was right eye 2/40 J. C. A. 1 to 20 J.

Visual field loss of all but the center. The patient can read only 20/40. The patient has seen this clearly.

We have definite evidence of severe damage to both occipital lobes and a note that all the area did not appear to be destroyed. The damage to the anterior stream from the area and undoubtedly to the center area.

In these patients we must be on the lookout for hysteria or exaggeration of the field defect despite the genuine severe injury. That they must have a large field defect due to injury but for some reason may have a small loss. A medical officer once told me of inspecting a patient with such a field of getting around too well. Under sodium amytal the patient confessed that he had a water field but because of a personal problem he elected to show this limited field.

So far as we were able to ascertain 2 of our patients actually had this type of field. Similar cases have been described by Gordon Holmes and by Scarlett and Ingham after World War I. McDonald has described bilateral homonymous hemianopsia due to bilateral occlusion of the calcarine arteries. A vertical strip of field was retained below the spared fixation area.

CASE 7 This patient showed field defects which are the antithesis of the last one. That is he has bilateral central scotomas with normal peripheral fields.

He was injured by shrapnel sustaining a depressed fracture of the occipital bone with multiple foreign bodies. The next day débridement of the wound was carried out. Three days later vision began to improve and did so for 2 months. Four months after injury the depressed fracture was elevated, pieces of bone and shrapnel were removed from the right occipital lobe. Both occipital lobes were lacerated and degenerated. Some of the cortex being replaced by xanthochromic scar tissue. Vision was 20/300 J. C. eccentric in each eye. The peripheral fields were normal. The central showed bilateral central scotomas with most of the cortex to the right of the midline. Injury to the cortex at the tip of both occipital lobes explains the left accounts for the field defect.

Gordon Holmes has shown a variety of homonymous central field defects both unilateral and bilateral.

brain and an intracerebral clot. Craniotomy was performed 2 days later followed by drainage of cerebrospinal fluid for a period of 4 weeks.

Röntgenogram of the skull showed an oval area of bony dehiscence measuring 5 by 3 centimeters in the posterior portion of the left parietal bone and anterior portion of the left leaf of the occipital bone.

The field defect was right homonymous hemianopia with sparing of the fixation area and a portion of the right field adjacent to the vertical meridian. Visual acuity was 20/15 J1 in each eye.

The site of injury data obtained at operation, plus the field defect indicate a lesion of the left occipital cortex, probably vascular in type. Sparing of fixation is due to the dual blood supply to the cortex.

CASE 2: This patient sustained a severe compound comminuted fracture of both leaves of the occipital bone with stellate fractures of both parietal bones. Multiple foreign bodies were seen at a depth of 5 to 6 centimeters in the left parieto-occipital area.

Craniotomy was performed the next day. Débridement left a 6 by 3 centimeter defect in the occipital bone. A hematoma and damaged tissue of the brain were removed. The foreign bodies were not removed from the left occipital lobe.

The patient was apparently blind for a period of 15 days, during which time both pupils reacted to light. He also showed sensory aphasia and generalised hyperreflexia. Bilateral papilledema was present for a considerable length of time before subsiding spontaneously.

Röntgenogram showed a 4 by 8 centimeter defect in the occipital bone, more to the left side. Linear fractures radiated in all directions from this defect. Two large foreign bodies were present in the parietal lobe 9 centimeters above the mastoid bone.

The field defect was right homonymous hemianopia with division or splitting of the fixation area. Visual acuity was right eye 20/70 plus 2 J12 and left eye 20/100 plus 1 J12. Degenerative changes visible in the nerve heads and maculae a result of prolonged papilledema account for the decreased acuity.

The information obtained at operation plus the field defect place this lesion in the left occipital cortex and deeper tissues of the brain. The sensory aphasia and hyperreflexia were due to damage to the parietal lobe.

CASE 3: This patient sustained a penetrating wound of the skull and both occipital lobes by a shell fragment which entered the left occipital and came to rest in the right occipital lobe. The foreign body was removed and débridement carried out.

X-ray examination showed a large surgical defect involving the inion and upper portion of the occipital bone—with fracture lines radiating into the left parietal bone and to both petrous pyramids.

Visual acuity was right eye ability to count fingers at 1 foot nasally and left eye at 3 feet temporally. There was conjugate deviation of the eyes to the right; pupils reacted to light; fundi were normal.

The field defect was right homonymous hemianopia plus a small central defect in each field. Dam-

age to the entire left visual cortex and to the tip of the right occipital lobe by the foreign body accounts for the field defect.

CASE 4: This patient was struck by mortar shell fragments, sustaining a compound, comminuted fracture of the occipital bone with depressed fragments driven into right occipital lobe of brain.

Two days after injury craniotomy was done. The tip of the right occipital pole and the calcarine area were destroyed by the fragment of bone. The dura was torn on both sides of the midline. The longitudinal sinus was thrombosed. The patient was unconscious for 11 days. Examination on about the fourteenth day showed complete blindness lasting several more days. Later the patient showed homonymous hemianopia by the confrontation method. The fundi were normal. Vision was reduced to ability to count fingers.

X-ray examination showed a 4.5 by 6 centimeter defect in the middle of the occipital bone with a stellate fracture extending into the right parietal bone.

The last field examination showed a left homonymous hemianopia plus loss of part of the right lower quadrants of the field and involvement of both fixation areas. The field defect is explained by damage to the right calcarine area and tip of the right occipital lobe. The left occipital lobe must have been damaged above the calcarine fissure with injury to the tip of the occipital lobe or the central fibers beneath the cortex.

CASE 5: This patient was injured in a plane crash, sustaining a compound, depressed skull fracture in the midoccipital region. Thirty-six hours later the depressed fracture was elevated. Two fragments just to the right of the midline were found 1.5 centimeters below the dura piercing the longitudinal sinus. A larger portion of the right leaf was peeled outward into proper position. The dura was intact except at the longitudinal sinus. The field defect 4 weeks later was a left homonymous hemianopia sparing the fixation area. Vision was 20/30 J1 in each eye.

Four months later the field defect was a left homonymous lower quadrantanopia with sparing of the fixation area. Vision had improved to right eye 20/15 J1 and left eye 20/20 J1.

Here we know that the right occipital cortex was damaged. The improved fields are explained by recovery from edema or contusion of the cortex adjacent to the destroyed cortex.

CASE 6: This is one of two patients with bilateral homonymous hemianopia with sparing of the fixation area and retention of good central vision in each eye. This patient was injured by artillery shell fragments, sustaining a compound depressed fracture of the left leaf of the occipital bone and several foreign bodies in the left frontal lobe of the brain.

On the day of injury the wound was débrided and the longitudinal sinus packed with muscle tissue to arrest bleeding. One week later the patient was completely blind, had a bilateral papilledema but his pupils reacted to light.

On the eighth day after injury a second craniotomy was done, evacuating a residual hematoma which was compressing the left occipital lobe by a centimeter. When the hematoma tissue was removed, a defect 3 centimeters deep remained. Then a dc was removed from the neck. Now all hope of cure was largely liquefied. The neurosurgeon's operative notes states: "There was considerable damage to both occipital lobes thus accounting for the blindness. The damage, however, didn't appear to me to destroy the calcarine area completely and it may be that after edema subsides vision may return, particularly in the upper fields."

Three weeks after injury the patient had light perception. Vision gradually improved. Eight months later vision was right eye 20/40 J 6 and left eye 20/20 J 1.

Visual fields showed loss of all but the central one degree. The patient can read only one letter at a time, but he says he sees this clearly.

We have definite evidence of severe damage to both occipital lobes and a note that all of the calcarine area did not appear to be destroyed. There must be damage to the anterior portion of the calcarine areas, and undoubtedly to the optic radiations.

In these patients we must be on the lookout for hysteria or exaggeration of the field defect despite the genuine severe injury. That is they must have a large field defect due to injury but for some reason may show too much loss. A medical officer once told me of suspecting a patient with such a field of getting around too well. Under sodium amytal the patient confessed that he had a wider field but because of a personal problem he elected to show this limited field.

So far as we were able to ascertain 2 of our patients actually had this type of field. Similar cases have been described by Gordon Holmes and by Scarlett and Ingham after World War I. McDonald has described bilateral homonymous hemianopsia due to bilateral occlusion of the calcaneal arteries. A vertical strip of field was retained below the spared fixation area.

CASE 7 This patient showed field defects which are the antithesis of the last one. That is he has bilateral central scotomas with normal peripheral fields.

The first of these is the fact that the
 world is not a uniform whole, but is
 made up of many different parts, each
 of which has its own life and character.
 The second is the fact that the world
 is not a static whole, but is constantly
 changing and developing. The third is
 the fact that the world is not a
 perfect whole, but is full of imperfections
 and shortcomings. The fourth is the fact
 that the world is not a self-sufficient
 whole, but is dependent on the love and
 care of God. The fifth is the fact that
 the world is not a single whole, but is
 made up of many different parts, each
 of which has its own life and character.
 The sixth is the fact that the world is
 not a static whole, but is constantly
 changing and developing. The seventh is
 the fact that the world is not a perfect
 whole, but is full of imperfections and
 shortcomings. The eighth is the fact
 that the world is not a self-sufficient
 whole, but is dependent on the love and
 care of God. The ninth is the fact that
 the world is not a single whole, but is
 made up of many different parts, each
 of which has its own life and character.
 The tenth is the fact that the world is
 not a static whole, but is constantly
 changing and developing. The eleventh is
 the fact that the world is not a perfect
 whole, but is full of imperfections and
 shortcomings. The twelfth is the fact
 that the world is not a self-sufficient
 whole, but is dependent on the love and
 care of God. The thirteenth is the fact
 that the world is not a single whole, but
 is made up of many different parts, each
 of which has its own life and character.
 The fourteenth is the fact that the world
 is not a static whole, but is constantly
 changing and developing. The fifteenth is
 the fact that the world is not a perfect
 whole, but is full of imperfections and
 shortcomings. The sixteenth is the fact
 that the world is not a self-sufficient
 whole, but is dependent on the love and
 care of God. The seventeenth is the fact
 that the world is not a single whole, but
 is made up of many different parts, each
 of which has its own life and character.
 The eighteenth is the fact that the world
 is not a static whole, but is constantly
 changing and developing. The nineteenth is
 the fact that the world is not a perfect
 whole, but is full of imperfections and
 shortcomings. The twentieth is the fact
 that the world is not a self-sufficient
 whole, but is dependent on the love and
 care of God.

The peripheral fields were normal. The central fields showed bilateral central scotomata with the largest scotoma to the right of the midline. Inguity to the cortex at the tip of both occipital lobes, especially the left, accounts for the field defect.

Gordon Holmes has shown a variety of homonymous central field defects both unilateral and bilateral.

THE FENESTRATION OPERATION

An Evaluation of Its Present Status

GEORGE E. SHAMBAUGH, Jr., M.D., Chicago, Illinois

THE consensus of published reports indicates that the fenestration operation has taken its place as an accepted otologic procedure for certain cases of deafness due to otosclerosis. In evaluating the scope of usefulness of the operation at the present time there are 6 important questions that we should try to answer

- 1 Which patients should be operated upon?
- 2 Which technique yields the best results?
- 3 How does the hearing after operation compare with a hearing aid?
- 4 Can the operation arrest or prevent the nerve degeneration of otosclerosis with stapes ankylosis?
- 5 What are the risks?
- 6 How permanent are the hearing improvements?

WHICH PATIENTS SHOULD BE OPERATED UPON

The first question of which patients should be operated upon has been discussed in the literature by a number of otologists with general agreement except on one point. Otologists who have had experience with the fenestration operation agree that the external and middle ear should be free from any active or recent inflammation; that the eustachian tubes should be normally patent; and that the drum membrane should be intact. They also agree that the ideal patient for operation has a stapes fixation with normal cochlear function as evidenced by the masked bone conduction audiogram within normal limits for the speech frequencies, with an air conduction audiogram averaging 40 decibels or more loss for the speech frequencies (Fig. 1). The point of disagreement lies with those patients who cannot be classed as ideal because one or more of the speech frequencies by bone conduction is be-

low the normal range. Should the operation be refused these patients as some have advised or should the otologist consent to operate if the patient clearly understands that he cannot expect to attain the 30 decibel practical level?

Last spring the American Society for the Hard of Hearing through Dr. Fowler mailed out to its members who had had the fenestration operation the following questionnaire (Fig. 2). To aid this evaluation of the operation from the patient's viewpoint two copies of the questionnaire were sent to each of my patients operated upon since I began this work 8½ years ago with the request that one copy be mailed to the American Society for the Hard of Hearing in Washington and the second copy be mailed to the Chicago society. Through the gracious co-operation of the Chicago society I have been able to study these replies.

Before presenting the results of this inquiry let me make it perfectly clear that I am fully aware of the errors inherent in any such attempt to evaluate a medical procedure, for patients are notoriously prone to psychological reactions that may distort their judgment concerning the value and results of any therapy. Nevertheless, it would be a mistake to disregard entirely the patient's subjective evaluation of his operation provided we also insist upon objective audiometric proof of a sustained hearing improvement.

A total of 853 patients operated upon by me were mailed the questionnaire, and 623 replies were received. These were divided into 5 groups.

Group I. Operation successful in all respects; hearing has remained improved; family regards operation warranted in view of the results; the patient does not now wear a hearing aid; the patient would have the operation performed again were he to experience the same results.

From the Northwestern University Medical School.
Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Fig. 1. Preoperative air and bone audiograms on a patient classed as ideal for operation, and postoperative air audiogram.

Group II Operation successful in that family regards it warranted by the results and patient would have it performed again for the same results but a hearing aid is still worn on certain occasions

Group III. Family regards operation as not warranted by the results but patient would

- 1 Name
- 2 Date of fenestration operation
- 3 By whom performed?
- 4 State of hearing immediately before and following the operation audiogram if available
- 5 State of hearing one year following operation audiogram if available
- 6 State of hearing at present time audiogram if available
- 7 Effect on hearing for conversation (Better _____ No change _____ Worse _____)
- 8 What is the opinion of your family in regard to the operation? In view of the results was it warranted? Yes _____ No _____
- 9 Do you still use a hearing aid? Yes _____ No _____
- 10 Would you have the operation performed again if you were to experience the same results? Yes _____ No _____
- 11 Will you please add any other comments you believe might be helpful to others contemplating the operation

Fig. 2. Questionnaire sent to patients who had had the fenestration operation.

have it performed again were he to experience the same results and he does not now wear a hearing aid

Group IV Too soon after operation to be able to answer all of the questions

Group V Failure Patient would not have the operation performed again were he to experience the same results

Of the 623 replies 516 or 82.8 per cent regard the operation as successful in all respects 25 or 4 per cent regard it as successful, but still use a hearing aid at times 7 or 1 per cent regard it as successful but the family is doubtful 8 or 1 per cent wish to wait a while longer before committing themselves 66 or 10.6 per cent regard the results as a failure (Table I)

TABLE I.—REPLIES TO QUESTIONNAIRE RECEIVED FROM PATIENTS WHO HAD HAD FENESTRATION OPERATION

	Replies	Percentage of total
Group I (Successful)	516	82.8%
Group II (Partial Success)	25	4%
Group III (Partial Success)	7	1%
Group IV (Undecided)	8	1%
Group V (Failure)	66	10.6%

Fig. 3. Preoperative air and bone audiograms and postoperative air audiogram on patient who regards the operation as successful but bone hearing did not reach the 30 decibel practical level.

When we study the individual patients who regard the operation as successful in all respects (Group I) we find that 303 of the 516 reached the 30 decibel practical level as a result of the operation 71 more were within 5 decibels of the practical level while 142 have a loss of more than 35 decibels for the speech frequencies. How can these patients regard the operation as successful? The answer is that many of them gained so much for the lower frequencies that they can compensate in part for their relatively poor hearing for the speech frequencies (Fig. 3). Others were so profoundly deafened before operation that the improvement has been of great practical value even though it failed to bring them to the 30 decibel level of practical hearing. In other words the number of decibels that a patient gains is important to him, as well as the final hearing level that he attains.

The second group is also of interest. These patients regard the operation as successful but they still use a hearing aid at times (Fig. 4). Here again we have patients with a profound preoperative loss some of whom were unable to wear a hearing aid because of their pro-

found loss, but who now obtain very good results with a hearing aid and therefore regard the operation as worthwhile. Many of these patients state that the hearing results from the operation far exceeded their expectations.

From our experience and observation we believe that the fenestration operation has 3 important fields of usefulness: first in patients with stapes fixation and normal hearing by bone conduction where we have a good chance of restoring practical hearing and second in patients who are profoundly deafened and show beginning nerve degeneration where we cannot expect to bring the hearing to the practical level but where with a definitely guarded prognosis, the patient will usually gain enough hearing to regard the operation as very much worthwhile.

The following classification of cases for operation is suggested:

Class A. Ideal Normal hearing by bone for speech frequencies. Prognosis 8 in 10 chances of a permanent hearing improvement within the 30 decibel practical level (Fig. 1).

Class B. Suitable but not ideal Normal hearing by bone except for one of the speech

Fig. 4. Preoperative and postoperative audiograms on a patient who regards the operation as successful because she can now wear a hearing aid with excellent results and before operation she could not use a hearing aid because of the profound hearing loss.

frequencies that shows a loss of 30 decibels or more. Prognosis 50-50 chance of sufficient gain to do without a hearing aid (Fig. 5)

Class C Experimental Two or more of the speech frequencies show a 30 decibel or greater loss by bone, but the Rinne test for the 1024 fork is negative. Prognosis A remote 1 in 10 chance of sufficient improvement to give practical hearing without an aid (Fig. 6)

Class D Unsuitable due to incomplete stapes fixation or to profound nerve degeneration. Prognosis Operation contraindicated

In all cases in which there is a substantial difference to the patient in the useful hearing in the two ears the poorer hearing ear should be selected for operation. If the poorer hearing ear falls in class B and the better ear in class A the poorer ear should still be operated upon first, and if the operation is successful making this the better ear the second ear may then be operated. As long as the fenestration operation has a chance of making the hearing in the ear operated upon permanently worse we are not justified in risking the patient's better hearing ear. If we cannot always improve the hearing

by the fenestration operation at least we shall not be destroying the patient's useful hearing

The bone conduction audiogram should always be made with adequate masking of the opposite ear

In selecting cases for operation the tuning fork tests are a valuable adjunct to the air and bone audiograms. These four tuning fork tests are particularly helpful

1 If the patient cannot hear the 64 fork at maximum intensity close to the ear the stapes may be regarded as completely ankylosed. If the 64 fork is audible by air at moderate intensity the stapes fixation is only partial and the fenestration operation is not indicated because there is too little to be gained. Later in the disease when the stapes is more completely fixed and the 64 fork is scarcely heard at maximum intensity or is not heard at all by air the operation may become indicated.

2 If the Rinne test with the 1024 fork is negative using masking of the opposite ear the hearing should be improved by the operation even though the patient is a B or C case.

3 If the Rinne test with the 512 fork using masking is positive the stapes fixation is only slight and operation is contraindicated

4 If the 2048 fork is not heard by bone using masking the prognosis is very poor and the patient should be considered a C or D case even with normal hearing by bone for the 512 and 1024 frequencies.

The otologist who is beginning this work will do well to confine his operations to class A cases. As his experience increases and his results improve he may consent to operate on class B cases, but only after the patient clearly understands the definitely limited prognosis. Class C cases are better not operated upon and if possible should be persuaded to wear a hearing aid

WHICH TECHNIQUE YIELDS BEST RESULTS

The second question that we should answer in evaluating the present status of the fenestration operation is Which technique yields the best results? This question cannot be answered until accurate statistics are available on the results obtained by the various techniques that have and are being used. It is our belief that the future rapid advancement of the surgical treatment of otosclerosis depends more than anything else upon the complete and accurate reporting of results by all otologists who advocate a new technique. There is no other way by which we may judge the relative merits of different techniques and there is no other way to protect ourselves and our patients from the hasty adoption of a new but inferior technique on the basis of vague misleading incomplete or hasty reports. So important to the future of this work is this question that I wish to devote part of this paper to a consideration of statistical studies as they apply to the fenestration operation.

A few years ago a group of otologists interested in the fenestration operation agreed to contribute their records for statistical analysis to compare the results obtained by different techniques. This co-operative undertaking soon proved unsuccessful because of the failure of some to contribute their records. I should like to propose that some larger organization with authority and prestige such as the American Otological Society or the

American College of Surgeons undertake an impartial study and investigation of results obtained by different fenestration techniques.

The surgical treatment of otosclerosis lends itself ideally to a statistical analysis of results because we can measure these results objectively in terms of decibels. First a uniform method of making audiometric tests and of keeping records should be recommended. Second there should be an impartial periodic spotcheck of the records and audiometric tests of each otologist to insure sufficient uniformity and reliability of records and statistics. Third, methods of statistical analysis and interpretation of results should be agreed upon and, fourth a periodic, perhaps annual publication of the results obtained by different surgical techniques will permit an accurate and scientific evaluation of their relative merits.

To encourage such a program to further the improvement and development of the surgical treatment of otosclerosis along scientific lines, my associate, Dr. Juers, and I offer to provide every facility for an impartial study and analysis of our records and results on all of our patients operated upon since we began this work 8 1/4 years ago. The system that we have used for keeping our records and for tabulating our results has proved satisfactory for our own purposes. In comparing our own results as we have modified the operation from time to time. This system might be applicable to the larger study that we propose.

To minimize the apparent hearing improvement between the first audiometric test and subsequent tests due to the patient learning how to respond to this examination the pre-operative hearing level is determined by 3 pre-operative tests made on different days except in rare cases in which patients come from distant places and only 2 pre-operative tests may be secured. The threshold of hearing for 512, 1024, and 2048 cycles from the three pre-operative audiograms is averaged as the pre-operative hearing loss for the speech frequencies. After operation the patient's hearing is tested at approximately 2, 4, and 6 weeks, and 3 months, 6 months, and 1 year after operation, and at least once a year thereafter for the rest of that patient's life. When the patient has come from afar it may be impossible to re-

Fig. 6 Preoperative and postoperative audiograms on patient classed as an experimental candidate for the fenestration operation.

bels gained for the speech frequencies with the time after operation of this test and the most recent hearing result with the decibels gained or lost for the speech frequencies the time after operation of this test, and the final hearing level. Every time a patient returns for an audiogram the strip with the above data is replaced with a new strip incorporating his latest test. To facilitate a statistical calculation of results colored indicators are used as follows:

Orange Hearing worse (loss of more than 10 decibels for speech frequencies)

Yellow Hearing unchanged (within 10 decibels of preoperative level)

Green Hearing improved but improvement subsequently lost.

White Hearing gain of 10 to 30 decibels for speech frequencies.

Blue Greater than average gain of 30 to 40 decibels.

Purple Exceptionally great hearing improvement of more than 40 decibels for the speech frequencies.

Pink Hearing within the 30 decibel level

Red Hearing within the 20 decibel level.

By means of these colored indicators one may find at a glance the percentage of good and bad results in the 90 cases tabulated on each board. A change of 1 decibel in a patient's audiogram may shift the result from one classification to another and since repeated audiometric tests always show a fluctuation of a few decibels any statistical calculation will fluctuate slightly from month to month. The general average however remains approximately constant with a given technique.

Until statistical material such as I have described becomes available on all techniques, we cannot answer the important question of which one gives the best results. We can only present our own data and hope that others do likewise. We invite any of you to check our records, our scoreboards, and to examine our cases at any time.

The technique which we are using at Northwestern University Medical School has been described recently in the literature. Briefly it makes use of the Lempert nov-ovalis fenestration operation with the addition of certain features to inhibit osteogenesis. These are

1 Enchondralization of the fenestra. By this we mean exposing the osteogenetically inert enchondral layer of the bony labyrinthine capsule as widely as possible beyond the margins of the fenestra. This is accomplished by removing the osteogenetically more active perosteal layer leaving the fenestra on top of a dome shaped mound

2. Scrupulous removal of all bone chips and bone dust particles from the region of the fenestra by means of (a) the use of continuous irrigation while making the fenestra, (b) careful search with the binocular loupe for bone chips on the periosteal surface of the tympanomeatal skin flap (c) the use of adequate magnification with the binocular microscope to remove the endosteum with its adherent bone particles from the mouth of the fenestra.

3 Avoidance of trauma to the endosteum within the margins of the fenestra, by using

adequate magnification with the binocular operating microscope while removing the endosteum from the mouth of the fenestra.

4 Thorough burnishing of the bone around the fenestra with the 14 karat hard gold burnishing burr

5. Avoidance of bleeding into the perilymph space by (a) strictly local anesthesia, (b) continuous irrigation (c) reinspection of the fistula after the flap has been in place for a short time to be sure there is no active bleeding under the flap at the completion of the operation.

During the past year the technique developed by us at Northwestern University has incorporated 2 features to decrease cochlear damage from postoperative serous labyrinthitis (1) elastic absorbent sponge packs kept under continuous pressure against the tympanomastoid skin flap for 6 days, (2) immobili-

Fig 6 Preoperative and postoperative audiograms on a patient classed as a permanent candidate for the fenestration operation.

bels gained for the speech frequencies with the time after operation of this test and the most recent hearing result with the decibels gained or lost for the speech frequencies, the time after operation of this test, and the final hearing level. Every time a patient returns for an audiogram the strip with the above data is replaced with a new strip incorporating his latest test. To facilitate a statistical calculation of results colored indicators are used as follows:

Statistical analysis of probably permanent hearing results in all patients operated upon by the Northwestern University improved fenestration technique.

zation of the cochlea for 6 days by a head frame to prevent it from being dependent to the fistula.

With this technique the incidence of bony closures has been reduced to less than 5 per cent of cases tested 2 years or more after operation (Table III). During the past year the incidence of postoperative serous labyrinthitis has been materially reduced (Table IV) with a definite gain in the hearing results. The final results with the sponge and head-frame technique must await the passage of at least 2 years.

HOW DOES THE HEARING AFTER OPERATION COMPARE WITH A HEARING AID?

The third question is: How does the operation compare with a hearing aid? One otologist stated that a hearing aid will do as much or more for the hearing without the discomforts, risks, uncertainties and expense of surgery. However, we have found that many patients who have had the fenestration operation and who regard the results as satisfactory assert without qualification that they hear better now than they did with their aid, and without the distortion, the nuisance and the upkeep expense of an aid. One patient writes: "The ear phone is a poor substitute for normal hearing." If this seems too obvious a statement, it

TABLE IV.—STATISTICAL ANALYSIS OF 300 CASES IN WHICH PATIENTS WERE OPERATED UPON BY THE IMPROVED FENESTRATION TECHNIQUE INCLUDING FEATURES TO DECREASE POSTOPERATIVE SEROUS LABYRINTHITIS

January 1946 to September 1946

	N of cases	30 db practical level	Average age at operation	Improved 10 db or more	Unchanged less than 10 db	Worse 10 db or more
Class A ideal	83	6%	41 db	66.5%	3.5%	1%
Class B guarded prognosis	6	20.8%	30.8 db	66.7%	3.3%	6%
Class C experimental	51	8.6%	30.4 db	67.2%	12%	0%
Totals cases	300	6.4%		67.2%	7%	7%

is only that I who have been through the looking glass of the distorted and undistorted reflection can hardly believe my ear now that it has been given back to me.

To try to compare a hearing aid with the operation by objective tests, 3 years ago we carried out speech reception tests in terms of decibels on patients with their hearing aid before operation and without their aid after operation. Even in cases in which the post-operative hearing did not reach the 30 decibel practical level we found that 7 patients who received a gain of more than 20 decibels for the speech frequencies understood speech better after the operation than they could before with their hearing aid. These tests may not have been entirely fair to the hearing aid, however, since a patient about to undergo the operation is not likely to invest in a new improved hearing aid. Further and more exact studies of this sort are now being made by Dr. Carhart of the Northwestern University School of Speech. The patients are being tested before operation with a well fitted hearing aid and the hearing for speech compared with the hearing after operation.

CAN OPERATION ARREST OR PREVENT THE NERVE DEGENERATION OF OTOSCLEROSIS WITH STAPES ANKYLOSIS?

The fourth question concerns the effect of the operation, if any, on the nerve degeneration of otosclerosis. This very important ques-

tion we cannot as yet answer with certainty. We can, however, make the following statements:

In cases followed for 5, 6 and 7 years after operation, where the fenestra remains open with a sustained hearing improvement further nerve degeneration in the ear operated upon has rarely been observed even when nerve degeneration had already begun at the time of operation.

When the fistula has closed with loss of the hearing improvement, nerve degeneration in the ear operated upon has continued to progress.

In a few cases with definitely progressive nerve degeneration in the ear not operated upon the ear operated upon has failed to show any evidence of further nerve degeneration.

We have reason to hope therefore that the fenestration operation may in some as yet unexplained way, arrest or prevent the second or any nerve degeneration of stapes ankylosis at least in some cases. The final answer to this important question must await further observations on a large number of patients successfully operated upon over another 5 to 10 years.

WHAT ARE THE RISKS?

The fifth question of the risks of the fenestration operation can be answered as follows. In more than 1300 consecutive fenestration operations plus 39 revisions carried out by myself and my associate, Dr. Juers, we have had no deaths and no serious infections.

The most frequent complication is transient facial paralysis coming on about 1 week after operation with complete recovery a few weeks later. This paralysis has occurred in 3 per cent of our operations. In 3 cases recovery was complete after 1 year but in no case did a complete paralysis remain.

Femoral phlebitis occurred in 4 patients during the first 2 weeks after operation with a pulmonary embolus in one. All recovered. To prevent this complication active and passive leg exercises are now a routine procedure in all cases.

Postoperative pulmonary atelectasis occurred after one of the early operations in which ether was used (Case 15). The patient recovered.

Schizophrenia probably incipient before operation became manifest after operation in one of the early cases (Case 23).

The chief danger of the operation is permanent damage to the labyrinth and particularly to the cochlea with persistent dizziness or with permanent depression of hearing below the preoperative level.

Dizziness sufficient to be annoying as a rule clears up within a few weeks. Rarely it lasts as long as 2 years. In only 1 case has it lasted more than 2 years; this patient complains of persistent ataxia and unsteadiness while walking $2\frac{1}{2}$ years after operation.

Permanent depression of hearing below the preoperative level has occurred to date in 37 operations (29 per cent of all patients operated upon) and in 1 of the 39 revisions.

HOW PERMANENT ARE THE HEARING IMPROVEMENTS?

The last question to be answered in evaluating the usefulness of the fenestration operation concerns the permanency of the hearing improvements.

Otologists who opposed the fenestration operation in its early stages of development did so on the grounds that the hearing improvements would never last because sooner or later bony closure of the fenestra would surely occur. As the result of animal experimentation and of clinical observation in many patients successfully operated upon and followed for more than 5 years we may now affirm what we previously hoped and that is that once healing has become complete osteogenesis tending to close the fistula ceases and a fistula still open may be expected to remain open permanently. In the monkey healing is complete and active osteogenesis has virtually ceased 3 or 4 months after operation in most cases. In the human bony closure occurs mostly during the first postoperative year occasionally during the second postoperative year and almost never later than 2 years after operation. A hearing improvement maintained for 2 years after the fenestration operation may be regarded as almost certainly permanent. Study of the hearing of patients successfully operated upon and followed for 5 years or longer shows how the improvement is

generally maintained without significant variations year after year. In some cases the greatest hearing improvement occurred 6 months after operation with subsequent hearing tests slightly lower indicating partial narrowing of the fenestra. After the second year however osteogenesis has ceased and the hearing improvement is maintained at a stationary level.

The ultimate fate of the hearing improvements 10, 20 and 30 years after the fenestration operation must await the passage of time. From our experience to date we are justified I believe, in assuming that the 2 year hearing results are permanent.

An evaluation of the fenestration operation includes a consideration of its limitations and shortcomings.

First, there is the fact known to all otologists but unfortunately not stressed in lay articles, such as appeared in *Hygeia* and the *Reader's Digest* that the fenestration operation virtually never restores the hearing to normal. The operation may be expected to restore about half the hearing that has been lost, provided the patient is suitable for operation.

Second, the results of the operation in any case continue to be unpredictable. With the best of preoperative indications, and the best of operative techniques failures still occur in some cases.

Third, the fenestration operation is technically difficult to learn and its results will vary more with the skill and experience of the individual surgeon than do most operations. The question of training and perhaps certifying fenestration surgeons is a difficult problem that needs attention.

Finally, the fenestration operation is a strictly elective procedure. A hearing aid may always be resorted to in cases which are not

suitable or in which surgery is hazardous on account of age, health, or nervous instability.

CONCLUSIONS

In our evaluation of the present status of the fenestration operation we have sought answers to 6 questions, as follows:

1. The operation is useful in two types of cases. The ideal case with stapes ankylosis and normal cochlear function where we may expect to restore practical hearing, the suitable, but not ideal case with stapes ankylosis and slightly impaired cochlear function where we may hope to gain enough hearing so that the patient can go without his hearing aid.

2. The judgment as to which technique is the best must await the publication of adequate detailed statistical data. The results obtained by us with the technique developed at Northwestern University Medical School are presented.

3. Subjectively most patients prefer the hearing after operation to a hearing aid and 82 per cent of cases operated upon by us regard the operation as successful and do not use a hearing aid. Preliminary objective tests seem to confirm the fact that patients who experience an average improvement generally understand speech better than they did with their aid before operation.

4. There is evidence that a successful fenestration operation may arrest or delay the nerve degeneration of otosclerosis in some cases but it is too early to be certain of this.

5. With a meticulous aseptic technique the risks of the fenestration operation have proved to be minimal. The chief risks are to the facial nerve and to the labyrinth.

6. The 2 year hearing results of the fenestration operation may be regarded as the permanent hearing results.

THE USE OF RADIUM IN THE TREATMENT OF CONDUCTIVE DEAFNESS

JOHN E. BORDLEY M D Baltimore, Maryland

IRRADIATION of the nasopharynx with radium or with radon is effective in the treatment of that type of conductive deafness which is due to obstruction of the pharyngeal end of the eustachian tube by lymphoid tissue. It is not effective in the treatment of other forms of deafness. This treatment is more effective when instituted early before inflammatory reactions and infections of the mucosa of the middle ear have progressed to the stage of fibrous fixation of the ossicles.

Persons with conductive deafness whatever the cause, hear better by bone conduction than by air conduction (i.e. the Rinne test is negative) and they usually have good hearing by bone conduction. The impairment shown by means of the air conduction audiogram may be essentially flat or may be considerably 'tilted' in the high or in the low tone ranges.

Conductive deafness results from any condition that seriously interferes with the transmission of air borne sound waves to the inner ear. The common causes of conductive deafness are lesions that interfere with normal movements of the middle-ear ossicles. On the basis of pathology three subdivisions may be made of the common lesions that interfere with ossicular mobility. The first is ankylosis of the footplate of the stapes by otosclerosis (Fig. 1) this is an irreversible lesion. The second is fibrosis of the mucosa of the middle ear to such an extent that normal movements of the ossicles are prevented by dense fibrous adhesions (Fig. 2) such lesions also are irreversible. The third common type of lesion the one present during the early period of tubal obstruction is reversible and is the one that can effectively be treated by irradiation of the nasopharynx.

The essential difference between the third type of lesion and the second type is the structure of the mucosal thickenings that interfere with ossicular movements. In tubal occlusion the mucosa is edematous and hyperemic, due to the negative pressure in the middle ear caused by lack of replacement of the air absorbed by the moist walls of the closed cavity. Only after the condition has persisted for a long time and has been aggravated by repeated low grade infections does fibrosis of the edematous mucosa occur to a degree sufficient to interfere permanently with ossicular movements. So long as the thickening of the mucosa is primarily edematous the lesion is reversible if normal aeration of the middle ear can be restored.

Unfortunately it is not possible to present sections of ears which have received irradiations for conductive deafness, because none of our patients has come to autopsy. The next two illustrations, however show what takes place in ears where there has been such failure in function of the eustachian tube. The first section (Fig. 3) is from the ear of a patient who had repeated attacks of otitis media and deafness. At the time of death her hearing was within normal limits. Her tympanic membranes were scarred and retracted and as the sections show the middle ear has a greatly thickened tympanic membrane and the mucous membranes are thickened and infiltrated with inflammatory cells. The second section (Fig. 4) is from a 16 year old boy with normal hearing. Otoscopic examination showed marked retraction of the tympanic membrane. The sections illustrate minimal changes with some thickening of the tympanic membrane and definite thickening of the mucous membranes of the middle ear especially over the promontory. Neither of these cases shows irreversible changes around the ossicular chain. It is quite easy to visualize how the first case could develop deafness when further

THE USE OF RADIUM IN THE TREATMENT OF CONDUCTIVE DEAFNESS

JOHN E. BORDLEY M.D. Baltimore Maryland

IRRADIATION of the nasopharynx with radium or with radon is effective in the treatment of that type of conductive deafness which is due to obstruction of the pharyngeal end of the eustachian tube by lymphoid tissue. It is not effective in the treatment of other forms of deafness. This treatment is more effective when instituted early before inflammatory reactions and infections of the mucosa of the middle ear have progressed to the stage of fibrous fixation of the ossicles.

Persons with conductive deafness whatever the cause, hear better by bone conduction than by air conduction (i.e. the Rinne test is negative) and they usually have good hearing by bone conduction. The impairment shown by means of the air conduction audiogram may be essentially flat or may be considerably tilted in the high or in the low tone ranges.

Conductive deafness results from any condition that seriously interferes with the transmission of air borne sound waves to the inner ear. The common causes of conductive deafness are lesions that interfere with normal movements of the middle-ear ossicles. On the basis of pathology three subdivisions may be made of the common lesions that interfere with ossicular mobility. The first is ankylosis of the footplate of the stapes by otosclerosis (Fig. 1) this is an irreversible lesion. The second is fibrosis of the mucosa of the middle ear to such an extent that normal movements of the ossicles are prevented by dense fibrous adhesions (Fig. 2) such lesions also are irreversible. The third common type of lesion, the one present during the early period of tubal obstruction is reversible and is the one that can effectively be treated by irradiation of the nasopharynx.

The essential difference between the third type of lesion and the second type is the structure of the mucosal thickenings that interfere with ossicular movements. In tubal occlusion the mucosa is edematous and hyperemic, due to the negative pressure in the middle ear caused by lack of replacement of the air absorbed by the moist walls of the closed cavity. Only after the condition has persisted for a long time and has been aggravated by repeated low grade infections does fibrosis of the edematous mucosa occur to a degree sufficient to interfere permanently with ossicular movements. So long as the thickening of the mucosa is primarily edematous the lesion is reversible if normal aeration of the middle ear can be restored.

Unfortunately it is not possible to present sections of ears which have received irradiations for conductive deafness because none of our patients has come to autopsy. The next two illustrations however show what takes place in ears where there has been such failure in function of the eustachian tube. The first section (Fig. 3) is from the ear of a patient who had repeated attacks of otitis media and deafness. At the time of death her hearing was within normal limits. Her tympanic membranes were scarred and retracted and as the sections show the middle ear has a greatly thickened tympanic membrane and the mucous membranes are thickened and infiltrated with inflammatory cells. The second section (Fig. 4) is from a 16 year old boy with normal hearing. Otoscopic examination showed marked retraction of the tympanic membrane. The sections illustrate minimal changes with some thickening of the tympanic membrane and definite thickening of the mucous membranes of the middle ear especially over the promontory. Neither of these cases shows irreversible changes around the ossicular chain. It is quite easy to visualize how the first case could develop deafness when further

swelling took place and secretions became backed up into the tympanic cavity.

The selection of patients suitable for treatment with radium can only be done with any accuracy by taking into consideration the history, the otoscopic examination, the nasopharyngoscopic examination and hearing tests. A very careful history must be taken. Fluctuating hearing and hearing much affected by upper respiratory tract infections or by changes in altitude or humidity are some of the common symptoms. Occasionally there is a history of frequent attacks of otitis media or a feeling of fullness in the ears. These symptoms are not necessarily bilateral. There does not have to be a history of mouth breathing. The deafness is usually progressive over a long period of time in spite of its fluctuations. The otoscopic examination may reveal a slightly thickened and retracted tympanic membrane, some retraction of Shrapnell's membrane, and a fluid level or the chicken wire appearance of mucous bubbles behind the tympanic membrane. The nasopharyngoscopic examination most frequently reveals hypertrophied lymphoid tissue in the fossa of Rosenmueller and around the eustachian orifice. Figure 5 illustrates a normal eustachian orifice which can be compared with one covered by such an overgrowth of lymphoid tissue (4). Occasionally very little more than congestion or mucoid discharge can be seen around the orifice. Hearing tests made with the audiometer and tuning forks are necessary to establish the diagnosis of conductive deafness. The audiograms usually contribute very little toward a differential diagnosis except in those few early cases which show an exaggerated high tone loss superimposed on the usual flat loss. About half of our patients show equivocal or just negative Rinne tests, with a 512 d.v. tuning fork.

Radium emanations are employed in the nasopharynx to reduce the amount of lymphoid tissue and combat the chronic infections involving the pharyngeal end of the eustachian tube (1). It is this tissue which acts as a focus of infection pointing toward the middle ear and likewise acts as a mechanical obstruction to the proper drainage and aeration of the middle ear. The backing up of infected secre-

tions into the middle ear results in a low-grade inflammation with edema of the membranes and excessive secretions. In time, this obstruction of the tube builds up a negative pressure within the tympanic cavity and causes retraction of the tympanic membrane. Such changes result in interference to the normal movement of the ossicles and a conductive type of hearing loss. Such conditions, if allowed to persist, lead to the formation of scar tissue and a permanent limitation of ossicular movement. The nasopharynx, then, is the danger spot that must be treated to relieve the symptoms of reversible conductive deafness. It is just as important to clear up the infection as to remove the mass of the tissue itself. Use of antibiotics in conjunction with irradiation is definitely indicated in some cases. Radium has been chosen by our clinic, first, because as Helneke showed in 1905 lymphoid tissue is highly sensitive to irradiation and second, because it offers a means of applying such rays locally in high concentrations without first passing them through normal surrounding tissues in which many of them will be absorbed. Thus the maximum dose can be delivered at the desired point and the possibility of injuring surrounding structures reduced. The action of radium is on the germinal centers of the lymphoid tissue. Also Burnam in a personal communication states that radium has a powerfully destructive effect upon the bacteria growing within this tissue.

To obtain maximum results, it has usually been necessary to administer repeated treatments with radium. We now use a series of three irradiations spaced a week apart. The dose used is calculated at 25,000 milligram seconds for the standard monel metal Army applicator or 17,000 millicurie seconds for the stainless steel radon gas applicator made by the Kelly Clinic. This difference in the calculated doses is due to the larger proportion of β rays that pass through the stainless steel. Both applicators are applied by simply inserting them along the floor of the nostril into the nasopharynx in close proximity to the eustachian orifice. Thousands of irradiations have been given in our clinic with no single serious reaction. Likewise, no serious reaction followed any of the 14,000 treatments given in the

Fig. 3. Section showing fibrosis around the ossicles, a thickened tympanic membrane, and edema of the mucous membranes of the middle ear. This section is from a 37 year old woman with history of reversible conductive deafness but with normal hearing at death.

tually able to determine this, the incidence of good results will show a marked increase.

Two cases have been chosen to illustrate reversible conductive deafness and what may happen when irradiation therapy is given. The first case (Fig. 6) is a boy aged 9 one of identical twins, who had begun to fail in school and who had a speech defect. He was thought to be mentally defective. His identical twin was leading the first division of this child's class. This child had had two adenoidecto-

Fig. 5. Photographs made through nasopharyngoscope showing, left, a normal eustachian orifice and, right, a eustachian orifice overgrown with lymphoid tissue. (From Hendricks and Lieberman 4.)

mies and a tonsillectomy. At times his family felt he had some deafness. There was no history of previous ear trouble. His tympanic membranes were severely retracted with scarring of Shrapnell's membrane. A mass of adenoids in the nasopharynx had completely overgrown the eustachian orifices. The bone conduction was excellent the Rinne test was negative on both sides. An adenoidectomy was performed with no change in his hearing. At the end of July he received his first irradiation and shortly afterward began to improve. By January his hearing was much improved (Fig. 6 second audiogram). His Rinne had become positive. Within 1 year his speech defect disappeared and he was with his twin in the first division of his class.

The second example (Fig. 7) is a 12 year old boy who had been deaf since infancy but the family had noticed a marked fluctuation of his hearing with colds. He had had no otitis.

Fig. 6. Audiograms showing hearing improvement which was gained in a 9 year old boy 5 months after first irradiation treatment of eustachian orifices was administered for conductive deafness.

Fig. 7. These audiograms illustrate the improvement in hearing resulting from treating a conductive lesion which was superimposed upon a congenital nerve deafness. In this case, bone conduction remained poor.

The tympanic membranes were dusky in color not retracted. The eustachian orifices were peppered with lymphoid nodules. His hearing showed an accentuated high tone loss. Bone conduction was shortened on both sides, but the Rinne test was negative on both sides. Following irradiation, it could be seen that he had nerve deafness with a typical Manasse type curve in his audiogram (Fig. 7) which had been depressed by a superimposed conductive lesion. His Rinne test became positive, but he still had a shortened bone conduction

CONCLUSIONS

The use of radium or radon offers an important additional type of therapy in the otologist's struggle against deafness. Like other methods of treatment, however it has definite

limitations and in order that its usefulness may be realized radium must be used within these limits. Treatment of deafness due to permanent ossicular fixation with radium is just as futile as doing a fenestration operation on a patient with no bone conduction. The key to the successful employment of radium is the careful and correct selection of cases. The history is as important as the examination. The earlier a patient is treated the better are the chances for improvement. The younger the patient, the more effective the irradiations will be. It is important to remember that radium treats the cause of eustachian obstruction and infection. It does not treat connective tissue lesions in the middle ear. It is effective in the nasopharynx, not at the oval window niche or the attic.

CONCLUSIONS

The use of radium or radon offers an important additional type of therapy in the otologist's struggle against deafness. Like other methods of treatment, however it has definite

limitations and in order that its usefulness may be realized radium must be used within these limits. Treatment of deafness due to permanent ossicular fixation with radium is just as futile as doing a fenestration operation on a patient with no bone conduction. The key to the successful employment of radium is the careful and correct selection of cases. The history is as important as the examination. The earlier a patient is treated the better are the chances for improvement. The younger the patient the more effective the irradiations will be. It is important to remember that radium treats the cause of eustachian obstruction and infection. It does not treat connective tissue lesions in the middle ear. It is effective in the nasopharynx, not at the oval window niche or the attic.

The danger to the future of radium therapy is in its overenthusiastic use by otologists not willing to take the care and the time to study each individual case. The indiscriminate use of this technique may bring it into disrepute. Its future is bright if we remember that a great number of patients lose their hearing each year as a result of nasopharyngeal infection and lymphoid hyperplasia, and it was for the prevention of such deafness that the radium applicators were first designed.

CONSIDERATION OF HEARING IMPAIRMENT IN THE TREATMENT OF CHRONIC SUPPURATIVE OTITIS MEDIA

J H MAXWELL, M D F.A.C.S Ann Arbor Michigan

THE degree of bearing impairment as associated with chronic middle ear suppuration varies greatly in individual cases. The amount of damage done to the middle and internal ear structures by acute infection at the onset, the extent of bone necrosis, and the interference with the sound conduction mechanism of the middle ear resulting from the healing process influence the loss of hearing acuity. There may be a conductive type of bearing loss of mild or severe degree, a mixed type of deafness if there is associated cochlear damage, or in some instances, a profound nerve deafness.

In the management of middle ear suppurations, the improvement of hearing or at least the preservation of residual hearing usually is not the major problem. The otologist is more concerned about the dangerous potencies of the infection from the standpoint of possible extension into the otic capsule or intracranial cavity. The patient's chief concern is more often associated with the annoying malodorous discharge. Although the bearing loss may not be the most important aspect of a case of chronic middle ear infection, it is not a factor to be ignored. In the case of bilateral middle ear disease the hearing loss may be of tremendous importance to the patient who may have to go through a complete rehabilitation program if further bearing impairment should develop.

How then should the otologist consider the problem of hearing impairment in his management of chronic middle ear suppurations? This question can be answered I believe by stating that first consideration should be given to the determination of the extent and dangers of the infection. Then other factors being equal, the treatment advocated should be that which will while dealing adequately with the

infection tend to preserve all residual hearing or even improve the patient's hearing acuity. This can be accomplished only by individualizing each case and adapting the therapeutic procedure to the individual patient. Many of us will agree that there has been a tendency to use rather routinely some form of drops or powder as 'conservative treatment' in cases of chronic otitis media. Then if the ear does not stop discharging a radical mastoidectomy is considered. Too many times this conservative form of neglect has been continued until intracranial extension of the infection has ensued. This form of treatment suggests that deplorable practice of adapting the patient to a routine therapeutic procedure.

In discussing individualized treatment from the standpoint of preservation of hearing, it is necessary that we understand the various major types of chronic suppurative otitis media and that we be able to recognize them clinically. It would be absurd for instance to use the same routine type of treatment in a case of so-called tubal ear as in a case of attic cholesteatoma. In each instance however the patient may complain only of moderate hearing loss and chronic discharge which may be continuous or intermittent.

The first uncompromising demand then in the management of a case of chronic suppurative otitis media is a thorough and painstaking clinical examination.

The history should if possible reveal facts regarding the onset of the discharge. It is well to know if the infection began before the age of complete pneumatization of the mastoid. If the infection originally complicated measles or scarlet fever or if the onset was insidious. One should ascertain any unusual symptoms accompanying acute exacerbations and bear in mind that intracranial complications usually develop during such recrudescences. The history of these episodes should reveal information relative to the typical danger signs of such

infection. These general signs and symptoms which have no place in a case of uncomplicated chronic suppurative otitis media and mastoiditis are as follows (1) hemicrania or generalized headache, (2) chills, (3) convulsions, (4) changes in sensorium, (5) extraocular muscle palsies (6) vertigo (7) nausea and vomiting (8) leucocyte count over 20,000 in adults and (9) marked disproportion of symptoms and signs. The existence of these signs past or present usually suggests an infection of serious nature.

Physical examination should include a complete and detailed study of the nose, nasopharynx, throat, and ears. The significance of the various types of perforations in the drum membrane and the various types of discharge must be understood by the otologist.

The therapeutic management should depend upon the position and extent of pathological changes present and upon the likelihood of extension of infection to the fallopian canal the inner ear or the intracranial contents. This information must be obtained from the clinical examination and not from an X-ray report only.

In the typical tubal ear demonstrating an anterior inferior perforation and a mucoid discharge the hearing loss is usually not profound, and if the ear becomes dry with concomitant thinning of the hyperplastic tympanic mucosa, the hearing is likely to improve. Since the major pathologic changes are hyperplasia, edema, and round cell infiltration in the tympanic mucosa, one need not be concerned immediately about the possibility of mastoid complications. Treatment should be directed

first to the nasopharynx from which hypertrophic adenoid tissue should be removed. In many instances the application of radium to the region of the eustachian tube orifices will have a beneficial effect. The local treatment to the ear should have cleanliness as its chief objective. Antiseptic solutions may be instilled daily by the patient. A saturated solution of boric acid in 70% alcohol used as ear drops is of value.

If there is fairly good evidence that the mastoid inflammation is minimal and that the tympanic mucosa is intact but secreting an abundance of mucus, X-ray therapy is often of considerable value. The prognosis on such conservative treatment is good even though there may be recurrence of the discharge during upper respiratory infections.

In the case of the large marginal perforation with granulations on the promontory but without granulation tissue or cholesteatoma in the attic there is, of course, hearing loss but if the ossicular chain is intact and the region of the stapedial footplate is free from granulation tissue, the hearing loss is usually around 30 to 40 decibels a level of rather serviceable hearing. In such an instance conservative local treatment may be continued indefinitely. The granulation tissue

fection of serious potentialities. The ossicular chain usually has been interrupted by necrosis of its component parts. The stapes or perhaps only its remaining footplate may be embedded in a mass of scar and granulation tissue. This type of otitis media is associated in most instances with bone necrosis, granulation tissue and perhaps cholesteatome formation in the tympanic antrum and neighboring mastoid cells. Hearing loss is greater than in the preceding type. Usually there is a loss of at least 50 or 60 decibels. In such a condition conservative therapeutic measures are of little value since the pathologic changes are deep seated. Radical mastoidectomy is frequently indicated, and this operation must be a precision type of procedure in which all diseased tissue is removed. One should expect to obtain complete healing in over 95 per cent of adult cases. The hearing will not be restored but it may be improved slightly 10 decibels or so if there is a large mass of granulation tissue in the middle ear before operation and if after healing the mesial wall of the tympanum becomes covered by thin skin. If there is but little granulation tissue in the region of the stapes before operation and after healing the promontory and region of the stapes is covered by a thick layer of scar the patient will suffer some increase in hearing loss. Occasionally a radical mastoidectomy may produce total loss of hearing in the ear operated upon. However if the disease is of such severity and extent that a radical mastoidectomy is indicated one should not procrastinate for fear the required operation may add to the patient's hearing impairment. To do so invites intracranial com-

plications. There is at least an even chance of preserving the residual hearing and this chance must be taken even if the disease is bilateral and of sufficient severity and extent to demand bilateral radical mastoidectomies. Too many times patients have been permitted to develop severe complications while a useless conservative medical form of treatment is being given a prolonged trial. The extension of infection along a pathway created by bone necrosis or by pressure atrophy due to cholesteatome formation takes place insidiously. The lack of pain or other untoward symptoms gives the physician a false sense of security while continuing the medical therapy. One must bear in mind the fact that the indications for radical mastoidectomy are present and must be discovered before a complication occurs. When the patient who has an old chronic suppurative otitis media develops a labyrinthitis, sinus thrombosis, facial paralysis, meningitis or brain abscess the physician knows and perhaps too late that he should have recognized the indications for operation weeks, months and perhaps even years before. Increasing hearing loss, profuse foul seropurulent discharge and episodes of pain and mastoid tenderness in a case of chronic otitis media almost always mean extending infection and impending complications. Mastoid tenderness is a most important sign of severe extending infection in the case of a small sclerotic mastoid. Roentgenograms should be made of course and they are of great value if well exposed and expertly interpreted but the indications for operation are to be discovered in the clinical examination.

Less common but most important, particularly in this discussion of chronic suppurative otitis media in relation to hearing impairment is the primary acquired form of cholesteatoma. There is apt to be a very small perforation in the flaccid portion of the tympanic membrane. There may be minimal and even unnoticed discharge except during exacerbations of the infection when there is characteristically a thin, foul smelling exudate. The attic contains a mass of cholesteatoma which may surround the head of the malleus and the body of the incus. In old cases the cholesteatoma may extend through the aditus into the antrum or expand downward into the tympanic cavity. The membrana tensa may be intact and show normal landmarks. A gray lusterless somewhat bulging membrane may indicate the presence of cholesteatoma in the lower portion of the tympanic cavity. The hearing acuity varies of course but in many cases in which the suppuration and mass of cholesteatoma are confined to the region of the attic, aditus,

and antrum there is less than 30 decibels of hearing loss. With the exception of those cases which are discovered at a time when only the attic is involved and which may respond to repeated attic irrigations this type of infection must be treated surgically. Obviously the instillation of drops or the insufflation of powder will be futile. The standard radical mastoidectomy will serve to cure the infection but will certainly cause an increase in hearing loss if the hearing in the involved ear is at a serviceable practical level. The operation of choice in such a case is a modified radical mastoidectomy. The atticomastoidectomy as described by Lempert has many advantages. This operation, which may be done by either the postauricular or endaural approach, permits of thorough excavation of the epitympanum after removal of the incus and amputation of the head and neck of the malleus. By severance of the tendon of the tensor tympani muscle the drum membrane may be retracted to give adequate exposure of the lower portion of the tympanic cavity if this is required. Preservation of the tense portion of the drum membrane which forms part of the tympanomeatal flap to be turned into the mastoid cavity assures the maintenance of a tympanic air space about a stapes which has not been disturbed. In well selected cases one can expect to obtain a perfectly dry healed ear and to preserve the hearing at a serviceable level.

Figures 1 to 7 demonstrate the preoperative and postoperative audiograms of patients on whom a modified radical mastoidectomy has been done for attic suppuration. In each case

INDICATIONS FOR SURGERY IN THE LIGHT OF THE USE OF ANTIBIOTICS

HARRY P. SCHENCK, M.D., F.A.C.S., Philadelphia, Pennsylvania

THE indications for sinus surgery have become greatly modified during a single decade because widespread clinical trial has demonstrated the ability of the sulfonamides, and later of the antibiotics, to modify profoundly the course of many acute and some chronic infections. Of the many known antibiotic substances only penicillin, streptomycin and tyrothricin have attained a position of therapeutic importance. To each of these can be assigned a specific therapeutic sphere on the basis of accumulated laboratory and clinical data.

In the treatment of some infections the sulfonamides and the antibiotics supplement each other. The antibiotics cannot be regarded as entirely replacing the sulfonamides. Fortunately the drugs of one or the other group may replace each other if the infecting microorganisms develop resistant strains or the patient exhibits sensitization. The advantages of economy and plentiful supply of the sulfonamides are generally outweighed by the comparative safety and absence of toxicity of penicillin and streptomycin especially in extremely ill or debilitated patients with liver and kidney damage.

The definite reduction in the number of sinus operations performed in the United States during the past 2 years is attributed to the effective use of chemotherapy in acute and chronic infections as well as in certain types of traumatic fractures of the paranasal sinuses. On the other hand the indications for surgical intervention in the presence of neoplasms or tissue alterations due to allergic phenomena have been little affected by the introduction of chemotherapeutic agents.

The antibiotics are of no value in uncomplicated allergy but they have been employed effectively against secondary infections complicating allergy of the upper and lower respira-

tory tracts. There is reason to expect therefore that bacterial sensitization may be forestalled in those instances where infection in an allergic individual can be arrested or eradicated by antibiotic therapy. On the other hand allergic patients are prone to become sensitive to the antibiotic drug itself and this is especially apt to occur when the drug is administered as a prophylactic measure over a long period of time. Sinus surgery continues to be necessary in the presence of advanced irreversible tissue changes in the nasal passages and sinus cavities if attributable to allergic influence alone and on the same basis as existed prior to the introduction of the antibiotics.

Certain advantages of properly applied antibiotic therapy are apparent during the preoperative period, the period of operation and the postoperative period of sinus surgery. In infectious sinus diseases effective antibiotic therapy during the *preoperative period* depends upon early and accurate diagnosis (especially accurate bacteriological identification) followed by selection of the antibiotic most lethal to the invading micro-organism, given in adequate dosage by the most effective route of administration and over a sufficient interval of time. Because antibiotic therapy frequently impedes or completely arrests the spread of infection, minimizes the occurrence of bacteremia and the toxic effects of active and overwhelming infection, there is an appreciable prolongation of the interval of safety between the onset of symptoms and the need for surgical intervention. The value of such delay is obvious in providing the opportunity for more thorough and detailed clinical studies—roentgenological, serological, and bacteriological.

A sense of false security may be engendered by the prompt therapeutic effects of the sulfonamides and the antibiotics especially in sinus infections in which irreversible tissue reactions have already occurred. Here recurrence is the rule as soon as chemotherapy is with-

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

drawn and although recurrent attacks may subside under further chemotherapy eventual surgery is inevitable in the majority of patients.

The administration of antibiotics in mild and transient sinus infections may eventually be regarded as poor therapeutic practice. It has long been recognized that immunity fails to develop when infections are promptly controlled by chemotherapy. Prompt arrest of bacterial activity prevents stimulation of immunological responses. As a result there are frequent recurrences at very short intervals. The tendency to readminister chemotherapy at each recurrence appears justified by the success attending its use in the first attack. Under these circumstances however repetition of chemotherapy fails to prevent progressive tissue changes, fosters the development of resistant strain of micro-organisms, and may sensitize the patient to the drug. In the latter event the drug is then disqualified for the treatment of a subsequent and perhaps more serious infection.

During the *period of operation* antibiotics used locally or systemically appear to have considerable prophylactic value by preventing meningitis, controlling bacteremia and protecting uninfected tissues in the operative wound from contamination.

In the *postoperative period* antibiotics limit the spread of infection to freshly exposed tissues and in most instances shorten the healing period.

Meningitis almost invariably follows *fractures of the paranasal sinuses* with a tear of the overlying dura. This complication can now be avoided by the prompt administration of the antibiotics and prompt surgical repair of the dura. When meningitis has already followed a fracture through the sinus wall with tearing of the dura, antibiotic therapy permits repair of the dural defect to be carried out after recovery from meningitis. Under these circumstances better clinical results are obtained by awaiting recovery from meningitis before proceeding with dural repair. Under continuing antibiotic therapy, fractures of the paranasal sinuses heal by primary union. Bone fragments, surrounded in part or entirely by viable soft tissues, exhibit amazing viability. However

bone fragments lying free within the sinus cavities require eventual removal. Sequestrum formation has been greatly minimized by antibiotic therapy.

The generally accepted rule that as little surgical intervention as possible should be employed in *acute sinus infections* has become even more rigid since the introduction of chemotherapy. Exceptions to this rule have been conceded in the presence of orbital extension, bacteremia and retrograde thrombophlebitis but the therapeutic use of the antibiotics has almost eliminated these exceptions because penicillin rapidly controls orbital cellulitis of sinus origin, clears the blood stream of viable organisms and impedes the progress of intravenous infection. More than ever before should acute sinus infections be permitted to become chronic before deciding upon surgical intervention. In many instances the antibiotics eradicate the infection before a chronic process can develop.

Antibiotic therapy in acute sinus infections must be confined to those induced by micro-organisms sensitive to the drug and it has become obvious that sensitivity tests should be carried out if possible prior to administration of the drug. Treatment of acute sinus infections due to resistant strains of micro-organisms fails to prevent progression to a chronic status and the eventual need for surgery. Prolonged therapy with a single drug may render the strain resistant, thus making it possible for infection to affect a previously uninvolved sinus during the course of antibiotic therapy.

Chronic sinus infections are resistant to antibiotic therapy because the drug penetrates with difficulty the abnormal tissues resulting from repeated or prolonged infection. Tyrothricin lacks the ability to penetrate tissue and its limitation to surface use renders its value in chronic sinus infections questionable. Even though penicillin and streptomycin can temporarily control the infection, recurrence often follows soon after antibiotic therapy is discontinued and ultimate surgical drainage is required. When surgery alone is unsuccessful in eradicating chronic infection in the sinuses antibiotic therapy is sometimes capable of playing a decisive rôle. The combined local and intramuscular use of penicillin after surgi-

cal failure brings about the disappearance of exudate and of viable micro-organisms. In most instances of chronic sinus infection in which irreversible tissue changes are extreme, a successful result can be obtained only by the combined use of surgery and chemotherapy.

In *meningitis* the ears and the paranasal sinuses are the most frequent primary foci. In the past, surgical drainage of the primary focus has been axiomatic in the treatment of meningitis. In most instances an initial attack of meningitis may now be controlled by antibiotic therapy with or without surgical drainage of the primary focus. This has led many clinicians to doubt the value of drainage of the primary focus when chemotherapy is available. At least it has become apparent that surgery can be safely delayed until the meningitis is under control. When surgical drainage of the primary focus is then attempted, precision laboratory and roentgenological studies have been completed and the patient has become a better surgical risk.

Relapsing cases of meningitis occur with more frequency in sinus infections than in mastoid infections. Even though operation may be of little value in the acute phase of meningitis, it continues to deserve consideration in the treatment of a relapsing case. It must be conceded that the full recovery of many relapsing cases can be attained with chemotherapy alone but the fact that the chronic focus consists of a formidable collection of pus, and perhaps sequestra, as well cannot be completely disregarded. Eventually such a focus must be dealt with surgically and especially when reinfection of the meninges coincides with discontinuation of the chemotherapy. Attempts to prevent relapse by sur-

gical attack upon an extradural source of infection have frequently been disappointing. Such failures seem more likely to be due to incomplete surgical drainage of a single focus or the presence of multiple foci which escape recognition. In the presence of an extensive focus surgical intervention cannot as yet be discarded in favor of chemotherapy alone. The concurrent use of chemotherapy and surgical drainage appears to be the best policy at the present stage of development.

Frank *osteitis* accompanying acute sinus infections has been generally controlled promptly by adequate doses of penicillin. Unfortunately reactivation of the infection may appear upon withdrawal of penicillin and extension to the meninges follows. When systemic penicillin is again administered, the effective control of the meningeal infection permits delay in operation. In fact surgical intervention appears to be most effective if postponed until the meningitis is controlled.

Penicillin rarely effects a cure in osteomyelitis of the frontal bone with or without brain abscess. Surgical intervention with maintenance of adequate drainage is imperative. The concurrent administration of intrathecal as well as intramuscular penicillin however has effected some remarkable recoveries. In spite of antibiotic therapy all necrotic bone must be removed before healing can occur. While the antibiotics exhibit a peculiar ability to relieve the pain associated with osteomyelitis, their main value lies in their ability to prevent sequestration and arrest progressive extension of the infection. In osteomyelitis secondary to sinus infection, the antibiotics seem capable of reducing the extent of radical surgery upon the skull to a remarkable degree.

EXTERNAL SINUS SURGERY

FRANCIS L. WEILLE M D Boston, Massachusetts

A REALISTIC approach to the problem of external sinus surgery is a prime requisite in any symposium on sinusitis. There are two reasons for this: the fear of the average layman engendered by advice for any sinus surgery especially by the external route and the necessity for the rhinologist to evaluate clearly just what he is offering the patient.

There is no question but that with modern chemotherapy many sinus operations—both intranasal and external—will be avoided. Yet in the presence of convincing evidence of necessity for an unavoidable external operation the rhinological surgeon must not only know certain common techniques thoroughly but also be able to evaluate them carefully before doing them.

In recently discussing the problem of external sinus surgery with a young well trained rhinologist who had graduated from one of the best otolaryngological hospital services about ten years ago, certain points of importance developed.

1 Although this doctor had had adequate training in both external ethmoidal and external frontal technique he felt far more confident of the excellence of his work in the former.

2 He had recently been compelled to do a Lynch frontal because of an orbital abscess which had failed to improve with chemotherapy. At operation he had done a complete ethmoidectomy and had drained a large frontal space which he had supposed to be the frontal sinus but which later turned out to be a very large frontoethmoidal cell. The frontal sinus itself was not entered at all. (But the very thorough ethmoidectomy was followed by uneventful cure of the patient!)

3 In several years army service in the recent war this same doctor had seen a number of cases in which simple trephination of the

frontal sinus had been done by civilian doctors *through the anterior diploetic wall!*

4 This led him to assume that many civilian specialists not only rarely do external surgery of the frontal sinus but that some rhinologists may not be too familiar with present day external techniques.

During the war the writer acted as consultant and assistant to a young rhinologist at a Lynch frontal operation and found it necessary to lend him technical aid. It was pointed out that the operator had opened a large frontoethmoidal cell which he had assumed was the frontal sinus; that there was inadequate exposure of the frontoethmoidal bony structure because of attempting to do the frontal sinus work first, independently of the ethmoid; that good exposure of the medial orbital wall was best obtained by detaching the medial palpebral ligament and elevating the periosteum; that in the Lynch frontal the easiest way into the frontal sinus is from the ethmoid by removing the lacrimal bone, and following the lacrimal and adjacent anterior ethmoid cells upward into the floor of the frontal sinus; that by having the patient sitting in a chair instead of lying on an operating table, he had in some respects made his task harder, etc.

In teaching internes external sinus surgery some of our more mature staff members have indicated their desire to review their technical skill. It may be desirable therefore to recapitulate briefly some of the surgical techniques used in external surgery of the sinuses.

THE FRONTAL SINUS

A *The Lynch operation*. Every rhinologist is familiar with the Lynch type of frontal operation. In the 15 years between 1930-1944 at the Massachusetts Eye and Ear Infirmary this was done 192 times in 447 frontal sinus operations on 276 patients (6). Therefore, in our hospital it is the commonest operation on the frontal sinus, with obliteration running second with 123 cases.

From the Department of Otolaryngology, Massachusetts Eye and Ear Infirmary.
Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

for a very few days or for many weeks and heavy dosage with penicillin used for the control of infection

The cleaner the healing field (less infection) the better. It is the infection factor which is a major cause for the proliferation of granulations (inflammatory and osteoid) and the inhibition of epithelial growth. The opposite process is required in surgical healing

THE CONTRACTURE PROBLEM

Early and late contracture are probably important in causing closure of the nasofrontal opening in both primary and secondary Lynch type operations. Late contracture is caused by shrinkage of collagen fibrils the less the granulation tissue and the quicker epithelization occurs in the region of the surgical nasofrontal communication the less likely is such contracture to be a factor. Early contracture begins after about 2 to 5 days progresses rapidly for several days, and then gradually subsides. It is early contracture which obturator-drains are supposed to lessen since such devices are removed in from 2 days to about 2½ weeks (1) by the majority of surgeons.

Anthony feels that such a device should be left beyond the secondary contracture phase of healing. The writer has a case with a permanently implanted tantalum tube in an unobliterated frontal sinus for over 2 years with no recurrence of trouble. A tantalum covered nasofrontal catheter left 4½ months in a tuberculous rhinitis case complicated by frontoethmoidal sinusitis and orbital abscess failed to establish satisfactory drainage and further surgery was required.

Primary or secondary contracture may be lessened by attention to the following granulation tissue surrounded by a circle of bone tends to contract toward the periphery of such a circle (Kazanjian) whereas granulation tissue surrounded by soft tissue only tends to contract centrally. The more nearly a nasofrontal opening in the Lynch procedure has a bony circumference the more likely it is to stay open. This merely means that so far as is consistent with thorough and adequate technique, the upper end of the ascending process and the nasal bone should be preserved.

In summary secondary revisions of Lynch frontals without obliteration require a certain amount of ingenuity a fundamental knowledge of surgical anatomy and of the surgical healing of connective tissue, bone and epithelium if obliteration is to be avoided.

C Obliteration Failure of the Lynch or Lynch type revision causes many experienced rhinological surgeons to consider obliteration as a solution to the problem. This means the collapse of the soft tissues of the anterior wall against the bony posterior wall or dura so that (a) no air space or gross mucoperiosteum remains in the sinus, and (b) the frontal ostium is sealed off by scar tissue with the result that (c) obliteration of the sinus results, together with (d) deformity relatively slight with a shallow frontal and severe with a large deep sinus. Sometimes obliteration is undertaken as an original procedure e.g. in the Mosher technique for excision of an osteomyelitic frontal squama, both sinuses were usually obliterated with removal of all walls. (The writer has not been compelled to remove the frontal squama in osteomyelitis since the release of penicillin for general use, but has had to obliterate the frontal sinuses in osteomyelitis limited to the sinus area.)

In every obliteration the anterior wall is removed from the frontal sinus. In addition, the floor may be removed or partly removed the posterior wall may be removed and in bilateral obliterations the interfrontal septum is removed. Mosher believes removal of the anterior and posterior walls and a little of the floor is most likely to succeed.

In obliteration it is desired to seal off any communication between the frontal sinus and the nasal cavity. If this is not an easy problem obliteration may not be necessary. In contrast the Lynch type of procedure makes every effort to establish a nasofrontal communication surgically. It is surprising that in Lynch or Killian operations, postoperative mucocoeles (or pyocoeles) were found to be commoner (13 cases) than after obliteration (3 cases) in a review of 276 external frontals at the Massachusetts Eye and Ear Infirmary between 1930-44. Such mucocoeles or pyocoeles are, in my opinion due to absence of nasofrontal drainage with secreting mucoperiosteum.

teum in the frontal area which produces a cyst

In 77 obliterative cases having osteomyelitis at the Massachusetts Eye and Ear Infirmary, 25 required further surgery. In 46 others having no osteomyelitis, 8 required additional operations directly upon the frontal sinus. This equals about 27 per cent failure for this type of procedure, as compared with 34 per cent for the entire group reviewed by the author in which all frontal operations of all types are included.

Incidentally, 71 of 123 obliterative cases required about 1.5 plastic procedures each for the repair of deformity, with an average of about 1 year's time for such work. The longest time was just over 5 years for 3 plastic operations in one of the cases.

D. Simple trephination of the floor of the frontal sinus with establishment of external drainage is useful in combination with chemotherapy in dealing with certain fulminating acute infections occasionally encountered. The frontal floor has no diploe except near its anterior and external margins and the trephine opening is made without disturbing this diploe. The frontal sinus lining is removed only at the point where the drainage tube is placed. Local and systemic penicillin therapy are carried out when the penicillin can be freely irrigated from the drainage tube into the nasal cavity and external drainage ceases, the tube is withdrawn.

After patient has recovered completely, he should have his nasal cavities made as mechanically and physiologically perfect as possible and further external surgery avoided if possible.

MacKenzie Brown (6) has reported treating certain chronic frontal sinus cases by simple trephination also.

E. The Jesberg and Lothrop operations are not commonly used in our hospital and will be omitted from this discussion.

THE ETHMOID AND SPHENOID SINUSES

External surgery of the ethmoid is no different technically from that of the Lynch frontal except that the frontal area is left undisturbed and the problem of making a nasofrontal communication surgically is thereby deleted. In both the Lynch frontal and the external ethmoid operations the sphenoid may

be opened and explored from its ethmoidal relationship if desired.

THE MOURE OPERATION

The Moure operation for excision of malignant tumors of the sinuses is a formidable undertaking. Its risks may be lessened by the following considerations:

1. Anesthesia is best given intratracheally with a balloon corking the glottis. Since oxygen is easily exploded by a diathermy apparatus, its use must be avoided. That is, air-ether mixtures are employed, not oxygen ether. This is accomplished by discarding the usual ether machine and substituting a large ether can which has several large holes made into its top, each hole being about the size of a dime. The intratracheal tube is attached to the mouth of the ether can and the patient's normal respiration sucks in air over the ether in the can with enough ether vapor to maintain surgical anesthesia. While the ether can be exploded by the diathermy apparatus, this risk is relatively slight with careful use of the machine. Both the nasopharynx and hypopharynx are packed with postnasal plugs secured externally through the mouth.

2. Both plasma and saline for intravenous use should be set up in the operating room and administered alternately throughout the operation. The anesthetist can most conveniently do this. Arrangements for transfusion to be done if necessary should be made prior to operation.

3. A highly efficient coagulation and cutting diathermy apparatus should be part of the equipment utilized. The writer prefers the large Davis Bovie machine.

4. The Moure incision is improved cosmetically and for practical exposure of the underlying field by making it slightly S-shaped. Its upper end starts at the lower aspect of the inner margin of the eyebrow and proceeds downward anterior to the tear sac region, then near the posterior margin of the lateral nasal surface to the posterior aspect of the ala nasi. It continues onward until the posterior margin of the ala nasi has been cut through and the nasal vestibule freed posteriorly almost to its medial aspect, the incision ending near the nasal columna posteriorly but

not involving the upper lip directly or opening into the vestibule. It is this last portion of the incision which allows very free mobilization of the soft tissues of the cheek to expose the pyriform aperture and upper jaw anteriorly. It will almost always avoid the necessity for making a transverse incision in the cheek. Bleeding is carefully controlled.

A line of cleavage around the pathological mass can usually be found by blunt dissection and this, plus diathermy cutting and coagulation will greatly limit blood loss. After getting the mass as widely dissected and freely mobilized as possible it is very quickly excised without regard to hemorrhage for the two or three minutes required for gross removal with the largest usable destructive instruments. Then hemorrhage is again quickly controlled and the removal continued until the tumor has been grossly excised and all suspicious areas coagulated with surgical diathermy. Adequate drainage into the nose is obtained if this has not already been accomplished by the excision of the mass. The wound is closed with plastic sutures without drainage externally.

Any sinus the nasal cavity and nasopharynx can be reached as desired by this approach as described or slightly modified. If the hard palate and alveolus are involved with the antrum alone, it is possible easily to reach as high as the orbital floor through appropriate mouth incisions and excise the mass without any external incision.

With highly radiosensitive tumors the Moure operation need not be done, since the simple provision for sinus surgical drainage plus adequate irradiation will suffice. In any event, a radiosensitive sinus tumor should be adequately irradiated whether or not the Moure operation is done.

POSTOPERATIVE CARE IN EXTERNAL SINUS SURGERY

In the hospital period of convalescence, ordinary surgical principles are followed for supportive treatment, including chemotherapy as seems necessary. If the wound has been

closed the sutures are removed about the third or fourth day if possible. If at operation the decision is made to leave the wound open because of the imperative need for control of sepsis, the surgeon *should be in no hurry to close it*. The patient's safety is of first importance. Incidentally surprisingly good cosmetic results are common in wounds left open for considerable periods of time.

Mosher's dictum "once a sinus always a sinus" does not correspond to the writer's experience if adequate follow up care is given the individual patient. Swimming and recurrent acute upper respiratory infections are common causes of acute exacerbations of sinusitis, which can be avoided or brought under control.

In polypoid sinusitis cases undue reliance is often placed upon the management of allergy. While every aid should be gratefully accepted the polypoid degenerative tissues will nevertheless sometimes recur massively. This problem is, at the present time, best solved by the use of coagulation diathermy to destroy such tissue as it appears, or removing small such areas periodically.

SUMMARY

The technique of several external surgical operations useful in sinus surgery has been summarized particularly the Lynch frontal operation secondary revision of postoperative frontal sinuses by a Lynch type procedure obliteration of the frontal sinus simple trephination of the frontal sinus incidental techniques for the external ethmoidal approach and the Moure operation. Some experience has been cited in evaluating these procedures. The Moure technique, for radical antrum surgery has been discussed.

INTRANASAL SURGERY

JOHN J SHEA M D Memphis, Tennessee

THE fundamental principle of intranasal surgery is the re-establishment of normal ventilation and drainage of the sinuses and when this can be accomplished by intranasal surgery it is preferable to radical surgery

ANESTHESIA

Local anesthesia is preferable for intranasal surgery. The patient should be buffered with a substantial dose of the barbiturates and a sedation dose of morphine. Whether atropine or scopolamine is used depends upon the operator's choice for the difference between the two is academic. A committee appointed by the American Medical Association reported in 1920 that they diligently studied the question of mixed local anesthetics and found that a single anesthetic was safer than combining a local as cocaine and infiltration such as novocain. Ether is a poor anesthetic for intranasal surgery but is safer for children than is any form of intravenous medication. Sodium pentothal combined with a local anesthetic is an ideal anesthesia for nervous patients.

SUBMUCOUS RESECTION

The correction of nasal obstruction constitutes more than 60 per cent of the intranasal surgery of today. Too often a rhinologist unconsciously asks himself during a nasal examination, "What do I see that I can correct?" His eye may discover a deflected septum or a hypertrophied turbinate and immediately that but of pathology is considered the cause of the patient's complaint. Early obstructions tend to retard the pneumatization of the sinuses and the normal growth of the alae nasi and upper maxilla. The paranasal sinuses can pneumatize normally with a complete occlusion of the vestibules or the choanae on the other hand an early septal deflection which jams the middle turbinate against the lateral nasal wall will obstruct the infundibulum

blocking the nasofrontal duct or the ostium of the antrum thereby arresting pneumatization of the sinuses which have their origin from this region.

Deviated septa occur more frequently in civilized races than among savages. Schaeffer states "The nasal septum encroached upon more and more by the forward cranial extension incident to brain growth as one passes from the anthropoids to the ultra-civilized races of man."

Headaches which are caused by nasal obstruction vary from slight nasal discomfort to severe neuralgias. The simple thickening of the septum high between the middle turbinates will interfere with the normal physiologic swelling of these turbinates. These patients appreciate their obstruction when they remain out-of-doors during cold weather or during an acute cold. This type of case receives a good result from a well performed submucous resection.

There is a deformity caused by a backward development of the sphenoidal process of the septal cartilage on a spur of the vomer. This large spur crowds the posterior fourth of the middle turbinate and is capable of persistent trouble. Whenever the middle turbinate enlarges, contact will be made and pressure exerted directly upon Meckel's ganglion. This is very noticeable during the menstrual period. The growth of this spur interferes with the size and shape of the middle turbinate and by extending laterally will encroach upon the ostium of the antrum. This deformity favors maxillary sinusitis by blocking the ventilation and drainage of the antrum. A good thinker needs a clear head. A dull child of hypertrophied adenoid is but an exaggeration of the adult with a blocked nose. The inability to breathe through the nose slows the cerebration and clouds the memory. As expressed in the words of Shakespeare "A man so dull, so dead in looks so woe begone."

The method and degree of packing after a submucous resection has ranged from none

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

through light, to metal clamps and tight pack- ings capable of being kept moist. If there occurs a small perforation or tear no precaution is necessary but if there is a bilateral tear whose edges are opposite it is recommended that a piece of Cargile membrane be placed between the flaps to serve as an arbor and also a barrier to the formation of a permanent perforation.

ETHMOIDAL LABYRINTH

An anterior ethmoidal cell migrates into the frontal to pneumatize the frontal sinus. In inflammations, allergic reactions or chronic degenerations of the anterior ethmoidal cells will block the frontal duct producing frontal sinusitis. The inward displacement of the middle turbinate is the simplest procedure to improve the drainage of the frontal sinus. Probing and irrigation of the frontal sinus was once a major procedure and before the days of good roentgenograms was hazardous and only attempted by the masters.

INTRANASAL FRONTAL OPERATION

The resection of the anterior end of the middle turbinate and the removal of hypertrophies and polypi of the middle meatus will give immediate drainage to a mildly blocked frontal sinus. If rupture of the sinus is eminent with a risk of an orbital cellulitis an external trephination should be done for immediate drainage. When the frontal empyema is chronic, the hypertrophies about the nasal frontal duct must be removed to maintain drainage. The resection of the middle turbinate is performed by resecting its anterior attachment and the removal of the tip with a cold snare. If there is a high septal deflection this must be resected to obtain sufficient operative space. The removal of the hypertrophied uncinat process and the adjacent ethmoid cells contribute to the exposure of the frontal duct. It is not considered good surgical practice to interfere with the lining of the duct for fear of future contractions. The post-operative treatment consists of irrigation of the sinus with antibiotic solutions. Many rhinologists initially irrigate with a peroxide solution as the offending bacteria are frequently anaerobic.

HALLE OPERATION

Halle's method depends upon the resection of a mucoperiosteal flap and the thorough removal of the agger nasi and sometimes a part of the process of the superior maxilla. The diseased anterior ethmoidal cells are thoroughly exenterated and the duct enlarged by burrowing and a resection of the floor of the frontal sinus. The flap is tamponed into the outlet and allowed to heal. This operation cannot replace the radical operation of Lynch when the lining of the frontal sinus is diseased but if a radical must follow the intranasal approach will be an added advantage.

Ingals designed a self retaining gold cannula to keep the nasofrontal duct patent and lately strips of tantalum have been advocated by Goodale to maintain the patency of the duct.

INTRANASAL OPERATION UPON THE ETHMOIDAL LABYRINTH

The appreciation that infections of the posterior ethmoidal cells and the sphenoid sinus were the causative factors in many of the optical nerve disorders prompted the perfection of operations designed at their exenteration. Mosher advocated removal of a portion of the middle turbinate to enter the ethmoidal labyrinth. The cells were curetted backward from above down passing from the anterior into the posterior group. This operation was the first of the American procedures to receive international recognition.

Ballenger's operation attempted to remove as much as possible of the ethmoidal labyrinth *en masse*. With a specially designed knife the ethmoidal labyrinth was carved free around its posterior superior and anterior borders and the resected mass was drawn from the nose.

The sphenothmoidal labyrinth is too delicate and its relationship to the meninges is too close to sanction such a radical procedure *en masse*. Then too there are so few perfect labyrinths, and the anatomic variations are so great that the method is limited to only selected cases in the hands of a very few surgeons. Hajek resected the middle and superior turbinate with his hook and reduced the anterior wall of the sphenoid and the posterior ethmoidal cells with the same hook, by insert

ing the hook posteriorly and drawing it forward, and removing the shreds with forceps. Sluder improved this technique by the use of his knife and removal of incised cells with a sharp biting forceps. Yankauer eliminated much of the bleeding by ligating the terminal branches of the sphenopalatine artery.

J. A. Pratt demonstrated that the exenteration could be accomplished without sacrificing the middle turbinate. When the middle turbinate and the ethmoidal cells were extensively removed the pathological process was eliminated but the ventilation of the nose was changed and the unrestricted air currents striking against the sphenoidal area frequently produced a hypertrophy of the anterior wall of the sphenoid sinus which obliterated it.

ANTRAL DRAINAGE

The resection of the nasoastral wall for drainage of the maxillary sinus is the simplest but frequently the best intranasal operation. The insertion of a hard rubber drain minimizes the size of the window and makes this operation acceptable for children. Robinson advocates compression of the antral membrane by a balloon for the cure of allergic sinusitis. Whether the anterior end of the inferior turbinate be amputated or displaced must vary according to the position of the floor of the antrum with relation to that of the antrum or the degree of hypertrophy of the turbinates. The operation can be spoiled by insufficient drainage or excessive ventilation with a loss of the physiological function of the turbinate.

POSTOPERATIVE CARE

The immediate complication of intranasal surgery is hemorrhage and the best method of its prevention is a well placed pack. The type of packing used should be impregnated with an oil and if it is to remain in over 48 hours it should contain some form of antiseptic. The ideal packing is so placed that the free ends remain outside the vestibule and folded within the nose to form a sac that cannot slip down into the nasopharynx.

If there has been free bleeding during the operation the terminal branches of the internal maxillary artery can either be coagulated or clamped off with small silver dural clips.

The center of the pack may be a cotton roll or splint capable of being saturated with a vasoconstrictor. If oozing continues after 30 minutes or begins freely after an hour it can be controlled by the administration of 5 minims of surgical pituitrin given hypodermatically every 15 minutes for 3 doses. Surgical pituitrin is also of value when administered before and after the nose is unpacked. Fortunately infections seldom complicate intranasal surgery but when they do occur must receive careful attention. Late secondary hemorrhage results from the separation of scabs and should be handled by the thorough cleansing of the nose of all clots, the control of the bleeding by adrenalin packs and the cauterization of the bleeding granulations. The use of oxycel an absorbable oxidized cellulose as an intranasal packing has the advantage of not requiring removal and is recommended for the invisible hemorrhage especially those from beneath the inferior turbinate.

CONCLUSIONS

The fundamental principle of intranasal surgery is the re-establishment of normal ventilation and drainage of the sinuses and when this can be accomplished by intranasal surgery it is preferable to radical surgery.

The generation of surgeons trained in intranasal surgery is fast fading and the number of these operations has been reduced by a better knowledge of the physiology of the nose and the therapy of antibiotics.

THE CLOSURE OF SURFACE DEFECTS WITH FREE SKIN GRAFTS AND WITH PEDICLE FLAPS

JAMES BARRETT BROWN M.D. F.A.C.S., St. Louis, Missouri

IN the Medical Department report of World War I, about 300 pages are devoted to plastic surgery no mention is made of free skin grafting however except that in one sentence a graft inside the mouth is suggested. Also no mention is made of the treatment of burns. In contrast to this, in World War II roughly one-third of the work in the centers for plastic surgery was the treating of wounds by free skin grafting and in addition a large volume of work was done in treating burn defects.

After World War I plastic surgeons in civilian practice developed methods and services for the repair of extensive burns, and except for a short time during which excessive attention was focused on the irreversible sealing methods of treatment (tanning) steady progress has been made in a basic philosophy of treatment of deep burns, viz. to make open areas as clean as possible as soon as possible and to restore skin that has been lost. Still further progress has been made in the concepts of treatment that aim at the start toward keeping burned areas clean. However the essential point remains that deep burns are apt

to become infected and certainly in military surgery they cannot all be kept ideally clean. There have been cared for in the plastic centers patients by the hundreds with no skin on their heads, faces, or hands and with large open areas over the body and extremities, with sloughs, contamination, infection, pain, and when evacuation has been delayed with the usual "blown" contamination that results from lack of change of dressing.

These patients present all the problems of nutrition chronic shock, blood chemistry and wound healing that may occur and these complications are all dependent on open wounds. Therefore the basic surgical consideration is to get the wounds healed as soon as possible, by means of free skin grafts. Any spontaneous healing that may occur is welcome, but long delay in waiting for spontaneous healing adds pain contractures, and fixation of joints, as well as a chance for further depletion. As large open wounds heal either spontaneously or by grafting the general condition improves proportionately. In some instances grafting has been done in spite of the presence of local infection uncontrolled by chemotherapy such a graft to close the wounds has been life-saving. Raw open areas as large as 200 square inches are frequently successfully grafted at one operation. These extensive procedures as well as others for the restoration of function in the words of one World War I surgeon would have been fantastic at that time.

While free grafts have been used most extensively in repairing burns, they have been applicable and valuable also to cover large open areas for other causes, such as gunshot and shell fragment wounds. One of the most important areas to benefit from free grafting is the hands. By early closure of burns and other defects of the hands, there have occurred many dramatic results in which function that otherwise would have been lost has been preserved. This statement applies to other ex-

Fig. 4. Chronic traumatic ulceration of both legs. Disabled many years. Complete healing following single operation with free skin grafts.

Fig. 5. Restoration of eyelids with full thickness grafts from clavicular region.

tremities. In some plastic centers, most of the work has been on the hands and extremities and only about one-third of the work has been on the face.

For making very extensive repairs, the split skin graft, or some version of it, must be used so that the donor site will heal promptly. In cases in which 250 square inches are transferred at one time it is essential that a method of grafting be used in which prompt healing of the donor site can be had. If grafts are cut too deep much added crippling may occur. In some instances it has been necessary to discharge patients because of trouble in donor sites that exceeded the original lesion.

A special area about the face may be mentioned and that is the eyelids. When eyelids are burned and contractures follow the eyeball is left exposed and impairment of vision may result. In hundreds of instances satisfactory protection of the eyeball by the lid has been regained with a free skin graft to resurface the lids. A special type of graft has been used for this work that is adaptable in function as well as color and appearance. Such a graft is of full thickness and is taken from the clavicular region—the supply is limited, but it affords the best color match and because of its character—presumably from its position in the platysmal area, gives excellent function.

Homografts have been used frequently to tide seriously ill patients over critical periods. These grafts, of course, are not permanent, usually lasting from 3 to 12 weeks. The wounds are literally "dressed" in the homografts. These grafts can be taken at autopsy if complete releases for the procedure can be obtained from the relatives and the patient. Such grafts have been taken as long as 4 hours after death and have been stored refrigerated for 6 more hours so that successful homografts have been done after as much as 10 hours delay. Longer periods have been recorded but the use of refrigerated skin has not been developed into a routine procedure.

Fig. 6. Direct flap restoration of full length of forearm. 8 days' fixation to the abdomen.

In the use of free skin grafts (as in other procedures in plastic surgery) a tendency has been noted to suppose on one hand that perfection can be obtained in difficult restoration of features and surface smoothness and on the other hand to neglect simple procedures in grafting that could result in healing of long standing lesions or deformities. For example one soldier was seen who had been off duty practically all of 9 years with traumatic ulcers of both leg. These were grafted in one operation and the patient was sent to duty.

In lesions for which free grafts will not suffice, such as gunshot and shell fragment wounds and in cases in which features are lost, restorations with pedicle flaps must be done. Whereas in the past the majority of flap repairs have been done with tubed flaps, it has been demonstrated in hundreds of patients that direct (or delayed) flat flaps can be used successfully. The principle of a short broad pedicle is substituted for that of a long narrow tubed one, and if the application can be made as a direct transfer (that is without delaying the flap) a procedure may be completed in days that otherwise might require months. This has accounted for the saving of thousands of patient hospital months.

One of the main usages for the direct flap is in the repair of hand and arm defects. The flaps can be put on at early dates following the injuries or later after the extremity has healed. It is possible to cover practically a whole forearm with a direct flap from the abdomen in 18 to 20 days and many seriously damaged extremities have been saved. It might be said that these procedures are the opposite of amputation. When applied early union of un-

derlying fractures has been found to progress more rapidly and successfully and function is necessarily established at the earliest date.

In late deformities with surface scarring and with defects of nerves, tendons, bones and joints, it is essential to obtain adequate surface 'healing' with a flap before satisfactory deep restorations can be done. The deep healing can be no better than the surface healing and patients have been seen with wire foil screws, plates, bone grafts and bone fragments protruding through wounds that did not have adequate surface healing. By removing dead and foreign material dissecting scar back to an adequate minute blood supply and making a repair with a flap of suitable thickness, so that the deeper tissues can be approached through good viable tissue that will heal promptly and protect whatever repair has been carried out on nerve tendon, bone or joint, the orthopedic or neurological surgeon has been afforded valuable assistance in his work.

There are details and variations of work too burdensome for this report but it is of importance to call attention to the fact that thousands of wounded soldiers have been successfully restored from serious surface defects by direct methods of free grafting and flap transfers.

The work has been done by many different civilian surgeons working in the services and in amount far in excess of any other period. Amputations have been practically nil as has also the operative death rate. Good team work is necessary between surgeons, nurses, anesthetists, rehabilitation workers and, of most importance, the wounded patient.

NEUTRALIZATION OF COLOR IN CAPILLARY HEMANGIOMAS OF THE FACE BY INTRADERMAL INJECTION (TATTOOING) OF PERMANENT PIGMENTS

HERBERT CONWAY M.D. F.A.C.S. and JOHN P. DOCKTOR, M.D. New York, New York

IN the treatment of capillary hemangiomas of the face the goal is the obliteration of the lesion so that appearance approximates normal. The authors' observations to date have led to the opinion that current methods of treatment including electrodesiccation, cauterization, radiation, sclerosing agents, and carbon dioxide snow are not satisfactory. Moreover, the plastic excision of such lesions from the face leaves much to be desired since usually it is necessary to resort to the use of a free graft of skin. Small grafts of skin taken from the postauricular area or from the supraclavicular area match the color of the skin of the face very well but if a larger graft is used this must be taken from a protected surface of the body the color match of which is not acceptable. Often such skin grafts on the face must be treated by the permanent injection of insoluble pigment (tattooing) into the derma in order to effect improvement in appearance. Therefore, the possibility of injecting pigments into the skin overlying capillary hemangiomas has been suggested. Results following permanent pigment injection of 7 cases of capillary hemangioma on the face are reported herein.

The process of tattooing for religious, ornamental or identification purposes is reported as far back as 2000 B.C. in Egypt and 1100 B.C. in China. Today mankind continues to practice tattooing for these same reasons. Natives of the jungles still use this practice as a method of tribal identification and civilized peoples still employ tattooing for physical decoration. The use of tattooing as a form of medical therapy can be traced to 1835 when

Pauli employed it in the treatment of nevus, congenital purple plaques and other lesions of the skin. Cordier (1848) advocated the tattoo treatment of nevus and Schuh (1858) had the idea of using skin previously tattooed and then transplanted to the site of repair in the practice of cheiloplasty. In 1879 de Wecker used India ink successfully in coloring the corneal parenchyma. Thirty-two years later (1911) Kollé reported the use of tattooing with rose pigment to change the contour of the vermilion border of the lip. He also pointed out that nonadherent, flat, white scars were improved in appearance by the use of tattooing. Knapp (1925) and Duggan and Nanavati (1936) used gold and platinum chloride to tattoo scars of the cornea. Pickrel (1946) has demonstrated evidence in color photographs of excellent results following the tattooing of the cornea. Credit is given to Morestin to Mauclair, to Dufourmentel and to Passot by Bankoff (1943) for introducing the treatment to general plastic surgery. In the recent literature Hance, Brown, Byars and McDowell (1944) called attention to the value of tattooing in the color matching of skin grafts and flaps on the face and in the simulation of the vermilion of the lip. Byars (1945) also reported successful intradermal pigment injection for color matching purposes in 60 cases of free skin grafts and flaps of tissue on the face. Brown, Cannon and McDowell (1946) reported improvement in appearance of one patient with a capillary hemangioma of the face following permanent injection of tattoo white and Chinese white.

TECHNIQUE

The area to be injected is washed with soap and water, painted with aqueous solution of merthiolate and draped with sterile towels. Instruments and pigments are sterilized. The

Fig. 1. Electromagnetic device with six needles which is used in the permanent pigment injection of capillary hemangiomas.

technician wears sterile rubber gloves. The area should be free from infection. It has been found expedient to use the standard electromagnetic device to which six needles are attached. This is shown in Figure 1. With sterile water the pigments are mixed into a thick paste which is picked up in the cup of the needle holder when the needles are withdrawn into its shaft. The current which causes rapid oscillation of the needles is operated by a foot control. The needles are inserted into the skin at an angle of approximately 60 degrees so that the pigment will be injected obliquely at varying depths in the derma. In the tattooing of skin grafts bleeding from the needle holes is minimal. Bleeding may be bothersome when injecting capillary hemangiomas. The basic pigments which are in use at present include the following:

White
Yellow
Red
Blue
Black
Green

Titanium (or zinc oxide U.S.P.)
Oxide of iron
Mercury sulphide (or cinnabar)
Cobalt blue
Black oxide of iron
Hydrated chrome oxide

Combinations of these pigments usually will produce the desired tints. In addition ochre sienna, and other earthy metallic oxides may be used. All of these pigments are insoluble and they may be sterilized in 70 per cent alcohol or may be autoclaved. The mixture of colors varies with the individual case. For the covering of capillary hemangiomas white is the basic pigment, occasionally mixed with a very small amount of red or green. At the first treatment, a small area is injected and a record is kept of the color combination. Three

Fig. 2. Low power photomicrograph of capillary hemangioma after injection of pigment. Note that the particles of pigment are deposited chiefly in the upper layers of the derma, superficial to the capillary dilatactions.

Fig. 3. Low power photomicrograph of normal skin tattooed for decorative purposes by a commercial artisan. In comparison with Figure 2 the pigment is more dense. It is scattered indiscriminately but is concentrated in the deeper layers of the corium.

TABLE I.—CAPILLARY HEMANGIOMAS TREATED BY TATTOOING

Case No.	Diagnosis	Size of lesion	Pigments used	No. treatments	Result
	Capillary hemangioma (cheek)	6 x 5 cm	White	3	Marked improvement
	Capillary hemangioma (cheek)	5 x 5 cm	White Green		Marked improvement; lesion barely perceptible
3	Capillary hemangioma (cheek)	8 cm	White	5	Marked improvement; lesion barely perceptible
4	Capillary hemangioma (cheek and eyelids)	9 cm	White Green Red	13	Result excellent
5	Capillary hemangioma (neck and cheek)	3 x 7 cm	White Green		Marked improvement; some scarring of skin
6	Capillary hemangioma (cheek)	3 x 7 cm	White		Marked improvement. Another treatment will be necessary over entire lesion
7	Capillary hemangioma (cheek)	no 9 cm	White	4	Improvement; still under treatment. One-third of lesion has been injected

to four weeks are allowed to elapse before judgment is passed on the effect of treatment. Usually there is some absorption or desquamation of pigment and a second or a third treatment over the same area may be necessary before the desired result is obtained. Following the treatment a sterile dressing is applied. The patient is seen in 24 hours at which time a crust is present over the area which has been injected. As this peels away during the next 6 to 10 days the effect of the injection may be observed. Once the proper combination is decided upon treatments may be given at 2 week intervals until the entire lesion is injected. An area of 2 to 3 square inches may be injected in a 1 hour sitting by a skilled technician. The number of treatments depends upon the size of the lesion. The injection causes some discomfort but the average individual tolerates this without anesthesia. In 1 case in the series, that of a child 3½ years old, the patient was admitted to the hospital and the treatment was given under avertin anesthesia.

OBSERVATION ON THE DEPOSITION OF PIGMENT

Figure 2 shows a low power microscopic section taken from a portion of a capillary he-

mangioma which had been tattooed (Case 1). The section shows a strip of skin with extensive tattooing and a rather fibrous corium. As noted in other examples, all colors of pigment appeared black occasionally with a reddish brown tint, on microscopic examination. It is impossible to distinguish the different colors either in stained or unstained sections. The pigment is scattered mostly in phagocytes in the upper layers of the corium. This figure is in contrast to Figure 3 which shows a low power microscopic section of skin taken from an area tattooed on the arm for decorative purposes by a commercial artisan. Here the pigment is much more dense. It is scattered more indiscriminately but is chiefly in the deeper layers of the corium and is massed about the ducts of the sweat glands. Study of microscopic sections of capillary hemangiomas leads to an understanding of the mechanism of color in these vascular abnormalities. The melanin which gives color to the skin is in the stratum germinativum of the epidermis. The vascular channels of the capillary hemangioma are in the subcutaneous tissue and to a lesser extent, in the deeper layers of the derma. The intensity of the red color of the great numbers of erythrocytes in the hemangioma reflected to the surface through the normal

Fig. 4. Case 4. a, Capillary hemangioma of cheek and eyelids. At the time of this photograph the lower portion of the lesion had been given treatments of pigment injection. b, Result after patient had been given 3 treatments. There was moderate, transient edema of the eyelid following the injections of pigment into the skin of these areas.

Fig. 5. Case 5. a, Hemangioma of the skin of the neck and cheek. b, Appearance after series of treatments

consisting of the injection of permanent pigments into the derma.

Fig. 6. Case 6. a, Capillary hemangioma of the cheek in a child 3½ years old. b, Appearance after one treatment consisting of intradermal injection of pigment. Avertin anesthesia was necessary. It was possible to cover the entire area in one treatment but complete obliteration of the color of the hemangioma was not effected. Further treatment is planned for this case.

Neutralisation of Color in Capillary Hemangiomas of the Face by Intradermal Injection (Tattooing) of Permanent Pigments—Herbert Conway and John P. Docktor
(Legend on opposite page)

pigment of the skin in its upper layers thus giving the effect of dark red to purple. In order to overcome the abnormal color of the capillary hemangioma it is desirable to concentrate the pigment in the derma, deep to the stratum germinativum of the epidermis and superficial to the vascular dilatations of the capillary hemangioma. Since Figure 2 and microscopic sections from other tattooed capillary hemangiomas have shown the concentration of tattoo pigment to be in the upper layers of the derma it is believed that any pigment which may have been deposited in the epidermis subsequently is lost through desquamation and that pigment which may have been injected into the capillary sinuses is carried off in the blood stream.

CASE REPORTS

Cases 1 to 7 are examples of port wine stains or capillary hemangiomas. As described by Lister these are sharply defined areas of intense erythema usually about the face and neck and not elevated above the surrounding skin. Present at birth they do not extend to involve new areas of the skin and they show no tendency to spontaneous regression. Table I lists the size and location of lesions, the number of treatments, the combination of pigments and the results.

SUMMARY

Report is made of 7 cases in which intradermal injection of insoluble pigment through electromagnetic needles (tattooing) has been used in the neutralization of the color of capillary hemangiomas. The management of these cases required a total of 40 treatments.

With one exception these treatments were done without anesthesia. The exception is the case of a 3½ year old child in which the single treatment was done under avertin anesthesia. There have been no complications. Microscopic sections of capillary hemangiomas so treated have shown that the desired result is obtained by injection of the pigments into the upper layers of the derma. All of the patients with capillary hemangiomas have been satisfied with the result of treatment. The technique of administration and a description of apparatus and pigments are given. Opinion is advanced that the intradermal injection of permanent pigments (tattooing) is a method of treatment which satisfactorily neutralizes the color due to capillary hemangiomas.

PRESERVATION OF JAW FUNCTION FOLLOWING SURGERY AND TRAUMA

LOUIS T BYARS M.D., F.A.C.S. and FRANK McDOWELL, M.D. F.A.C.S.,
St. Louis, Missouri

OPERATIONS on or trauma to the jaws the adjacent cheeks, or in the neighborhood of the joints may jeopardize function. The mandible, being the moving member is the part usually causing the most concern.

Removal of a section of the mandible creates an immediate and serious problem in management of the remaining fragments (1). If not controlled and held in proper relationship the attached muscles may pull the fragments medially and backward allowing the tongue to fall back in the throat and shut off the airway (Fig. 17). When such a patient survives the initial breathing and feeding hazards, the secondary repair of the bony defect is needlessly complicated by the necessity of laboriously restoring the fragments to their original relationship before the bone graft can be done (Figs. 7-12). This is particularly difficult when the posterior fragment has been pulled up into the temporal fossa and fixed there by

shortened muscle and scar. An unnecessary oral fistula may further complicate the problem prolong the rehabilitation, and make the patient miserable. Such operations often entail the loss of soft tissue with the formation of binding scar. Even resection of the part thickness of the mandible may produce this same result, if not this extreme, at least causing a loss of the buccal sulcus and inability to wear a denture.

Mandibular resection is usually performed as a planned procedure so that an adequate scheme is prepared in advance (1). Occasionally however one may be faced with the traumatic loss of bone creating the same problem. Where available, the simplest and best procedure is simply to wire the teeth of the fragments to their corresponding maxillary teeth (Fig. 12). Table IA indicates the mechanical possibilities where both fragments contain teeth. When partially or wholly edentulous, or in children where the teeth are not adequately developed the problem is more difficult and the schemes available without preliminary preparation are few. The appliances adapt

Fig. 1. Result following resection of the mandible for early osteogenic sarcoma. The mandible was resected and an internal bar inserted, the patient leaving the hospital entirely healed within 4 days. The bar is in place as shown 4 months after operation. There is no drainage and no evidence of bone reaction. Patient is allowed to chew soft foods. The mandible feels reasonably solid to palpation and there is only slight deviation of the chin on opening of the mouth. Eventually bone graft will be required if the malignancy proves to be controlled.

Fig. 2. Result following upper neck dissection, resection of the mandible and a large area of buccal mucosa for a carcinoma arising on the alveolus. Internal bar was inserted at operation as shown. Patient was healed within 6 weeks and returned to work within 6 weeks after operation. The bar is present without reaction or drainage 10 months after operation. Eventually the bar will probably be removed or supplemented with a bone graft.

ble to this problem are outlined in Table I—B and C.

TABLE I.—APPLIANCES USED TO CONTROL FRAGMENTS OF MANDIBLE AFTER RESECTION

- A
- Appliances which utilize teeth (intraoral) posterior fragment contains teeth
- Interdental wires.
 - Arch bars.
 - Swaged metal splint (with or without jack-screw)
 - Splint on teeth with dependent part separating bone
- B
- Appliances which utilize bone and teeth (intraoral and extraoral) short edentulous posterior fragment
- Wire teeth in occlusion and use modeling compound in molar area to keep posterior fragment down.
 - Arch bar or splint with posterior fork to keep posterior fragment down.
 - Arch bar or splint on mandible with posterior portion accurately fitted to junction of body and anterior border of ramus. (Herpin splint with or without jack screw)
 - As in (c) except arch bar or splint applied to maxilla with interdental wiring.
 - Arch bar or splint with posterior part attached
 - Directly to bone.
 - To bone screw
 - Wire passed through drill hole near angle of mandible and attached posteriorly to head cap and wire rest of jaw in occlusion.
- C
- Appliances which utilize bone (intraoral and extraoral) Number of teeth and size of posterior fragment not necessarily a consideration
- Bone screws (and bar) inserted with each fragment. (Stader Berry Griffin, etc.)
 - Intraoral.
 - Extraoral (preferred)
 - Kirschner wires (modified) passed through fragments.
 - Bar interposed between ends of fragments (Figs. 1, 2, 3, 4, 5, 6, 17)
 - Open bite splint attached with circumferential wires.
- Also controls fragments adequately for insertion of bone graft.
- †Not ideal for bone graft because of local osteomyelitis around bone screws and subsequent loss of stability of splint.

Because of the difficulties involved in repair following jaw resections it is desired to call attention to the operation of subperiosteal resection (2). It has frequently been observed that the mandible will regenerate with surprising adequacy after the sequestration of large segments following osteomyelitis (Fig. 16). Similar regeneration will occur following subperiosteal resection (Figs. 3, 4, 5).

Obviously this procedure cannot have widespread application. Subperiosteal resection is inadequate in the treatment of many tumors; it could rarely be safely performed in the treatment of any of the malignancies. Occasionally in dealing with adamantinomas, os

Fig. 3. a, Photograph of 8 year old child before operation showing enlargement of right jaw. b, 11 months after subperiosteal resection of the mandible. Microscopic diagnosis of tumor removed was ossifying fibroma. (J. C. and Reconstructive Surg. 1946, 1: 238.)

Fig. 4. a, Preoperative roentgenograph of tumor. b, Immediate result of subperiosteal resection. c, X-ray film taken 8 weeks following subperiosteal resection and insertion of internal bar. A strand of lingual periosteum was preserved which supplied regeneration as shown in this

short period of time. Wound has healed 10 days after operation. There has been no subsequent inflammation or drainage, and at the end of 26 months, the bar is still in place and the mandible strongly healed. (Plastic and Reconstructive Surg. 946, 1: 238.)

sifying fibromas, osteomas or even with more simple tumors which have caused extreme expansion of the bone, the entire thickness of the bone must be removed but some strands of periosteum can be left bridging the gap between the ends. If the fragments are adequately controlled regeneration will readily occur especially in children (Figs. 3, 4, 5).

In dealing with children splinting or interdental fixation is unsatisfactory. The same may be true in adults if the fragments are wholly or partially edentulous. In such cases holes may be drilled in the ends of the bones and a bar of stainless steel inserted to bridge the defect (Figs. 1, 2, 3, 4, 5, 6, 17). Surprising rigidity results from this procedure and al-

Fig. 5. a, Tumor of mandible in a 9 year old boy. At operation it was found that the entire thickness of the mandible was expanded and it seemed impossible to remove the tumor adequately and retain any bone at the tumor site. The periosteum was not involved except near the alveolus. A subperiosteal resection was performed and an internal bar inserted. The wound was completely healed in 10 days. No interdental fixation was required. b, Regeneration present 7 weeks following operation. Repeated ray films have been made to date over 18 months' time. No evidence of bone reaction is present. Wound is healed. The bar is still in place and there is no external deformity. (Plastic and Reconstructive Surg. 946, 1: 37.)

Fig 6. Roentgenogram of mandible of an 83 year old man following operation for carcinoma of the buccal mucosa and alveolus with metastasis to the upper neck. Oral portion of dissection was done with the cautery. An interal bar was inserted as shown. The neck wound was packed open because of the cauterized wound which was present. This healed down to a very small oral fistula which was closed 4 months after the operation. Although there was no reaction around the bar. It was removed at that time, having served its purpose of maintaining normal position of the fragments during the period of soft tissue healing. Especially in older people it is important to maintain the rigidity of the mandible during the immediate postoperative period to minimize respiratory difficulties.

Fig 7. a, c, Front and profile photographs of a patient who had lost anterior portion of the mandible from bicuspid to bicuspid area and soft tissue of the lip, chin, and floor of the mouth as the result of a gunshot injury. Note the narrowness of the face over the region of the angle of the mandible, the result of the remaining portions of the mandible being pulled inward by scar. Two previous attempts

at bone graft elsewhere had been unsuccessful because of the inadequacy of the soft tissue covering. b, d, Front and profile views of the same patient following restoration of soft tissue lining of lip and floor of mouth and covering of the chin and successful bone graft as shown in Figure 8. The lower lip was filled out by a triangular flap rotated from the center of the upper lip. Patient is wearing dentures.

Fig. 9. a, Huge ameloblastoma of the right mandible of 5 years duration. b, Result following hemisection of mandible. There has been no bone restoration. The deviation of the remaining portion of the mandible from the midline is minimized by accurate closure of the wound, and maintenance of remaining fragment in normal position during the period of healing and subsequent scar tissue pull (Surg. Gyn. Obst., 945, 5-577)

Fig. 10. a, Defect of face, palate and lining of cheek resulting from radical operation for carcinoma of the antrum. Patient has inability to open the mouth because of fixation of the coronoid process in operative scar. Applicator sticks are inserted in skin lined pocket underneath forehead flap which has been prepared for use in soft tissue repair. b, Final result obtained by restoration of half of the palate and buccal mucosa, letting in the flap through the hole in the cheek. Mouth opening was obtained by intraoral resection of the coronoid process. Another section of the same flap was used to fill the cheek defect after severance of the pedicle from the portion reconstructing the palate.

though additional fixation is desirable for a time, if available, it is not essential. Where possible, the mucous membrane should be accurately closed to exclude the neck wound from mouth contamination.

Following the conventional resection of the mandible the space retention apparatus must be worn long enough to insure that the fragments may be easily restored to their proper positions at the time for bone grafting. At such time some other scheme for fixation may be employed, possibly even utilizing the graft for partial fixation.

Soft tissue considerations before a bone graft to the mandible is done, adequate soft tissue covering for the graft must be present (Fig. 7). At the time of injury or resection all possible soft tissue must be preserved. This entails accurate closure of wounds and avoidance of continued infection with resultant wasting of tissues (Figs. 9-14). If the quality or amount of soft tissue is inadequate to cover the graft easily and heal readily afterward it

must first be supplemented with a skin graft, pedicle flap or by mobilization of local tissues (Figs. 7-8).

Because of the nature of the defect following resection of the mandible, the graft must be of the onlay type applied along the inferior and lateral borders of the mandible and overlying the bodies of the fragments. If it is desired to place the graft between the ends of the bones, anatomically replacing the resected segment, then a pedicle flap must be used intraorally between the ends of the bones to provide a good strong covering which will not be torn at the time of the dissection for the placement of the graft (Fig. 8).

Fig. 11. a, Front and profile view of a man 35 years old who has had ankyrosis of the left temporomandibular joint since childhood. b, Correction of asymmetry of the mandible

with cartilage transplant to make the chin more prominent and alleviate flatness over right mandible. Mouth opening was gained by resection of left temporomandibular joint.

Fig. 6 a, Osteomyelitis of the mandible with pathological fracture. b, Beginning regeneration of mandible following spontaneous sequestration and control of infection by conservative means. c, Adequate regeneration of the

mandible 4 months after acute infection. There is no external deformity. Radical surgery with removal of bone before spontaneous sequestration could surely have resulted in lack of continuity of the bone necessitating bone graft.

of such a scar and covering the enlarged defect with a free skin graft if it is superficial or a pedicle flap if deep will give permanent relaxation (Fig. 10).

Subsurface scarring in the region of scant clearance between coronoid process and zygomatic arch may cause firm fixation in a closed position. This may result from operation, infection or the use of radium in this neighborhood. Adequate resection of the coronoid to release one point of scar anchorage will give relief (Fig. 10).

Not infrequently mandibular resection with widespread soft tissue destruction is performed in cancer patients where restoration of mandibular continuity is not contemplated. Here it

is desirable to maintain function as far as possible. Internal bar fixation as described under subperiosteal resection has been very valuable under these circumstances, inasmuch as the remaining fragments are retained in normal relationship preventing immediate pharyngeal collapse with its dangers. Such fixation has been maintained without difficulty for several months eventually working free. During this period however the open wound has healed without the contracture which would pull the remaining fragment well out of position had not such fixation been maintained. Even though the patient's age and disease may not warrant complete repair the disability has been minimized (Figs. 2, 6, 17).

Fig. 17 a, Roentgenograph of Gliosarcoma of the zygopharynx. b, c, Roentgenogram showing resected area of the mandible with stainless steel internal bar fixation. The repairs around the hyoid bone and holds the larynx

forward to permit normal breathing. c, Resection of the zygopharynx region are especially hazardous. A new scheme is utilized to maintain the function of the zygopharynx and glossohyoid muscle groups.

Surgery, trauma, or infection in the neighborhood of the temporomandibular joints may result in either bony or fibrous ankylosis of these joints (Fig. 11). The intraoral use of radium or radon in this area may lead to such a condition. Frequently in addition to the joint obliteration the coronoid may be anchored to the zygoma (Fig. 10). In such conditions adequate resection of the joint, including the coronoid process if necessary, will give relief. More dependence should be placed in the adequate removal of bone at the site of resection than in the application of some substance between the resected ends. If adequate bone is removed the masseter muscle on the outside and pterygoid muscle on the inside will naturally fill the dead space between the cut ends, the amount of bone removed preventing reankylosing.

Under some circumstances this resection may be done from within the mouth. It is often more practical to make the approach from in front of the ear, reflecting the facial nerve downward, outward and forward or from the neck, elevating all soft tissues including the facial nerve from the ramus of the mandible and beginning the resection on the ramus above the angle and working up to include the condyle and coronoid process. In

some cases of ankylosis this is not too much bone to remove. Resection of the ramus of the mandible above the angle causes very little dysfunction and does not disturb dental occlusion as does resection of the body.

To wear dentures successfully the following factors must be considered: adequate mouth opening, mandible in continuity, adequate alveolar ridge and buccal sulcus to seat the denture, soft tissue of adequate quality covering unavoidable irregularities, upper and lower arches of proportionate size (Figs. 13, 14).

The presence of other anchoring teeth may be of help in making up for some other deficiencies.

Following loss of soft tissue within the mouth or local removal of part thickness of the mandible the prominence of the alveolar ridge may be lost. In such an instance an adequate incision in the buccal sulcus and application of a split thickness skin graft may be adequate. One must plan for considerable shrinkage in such a graft.

STUDIES IN THE ANATOMY AND REPAIR OF CLEFT PALATE

G M DORRANCE M.D. Sc.D. F.A.C.S., and J W BRANSFIELD M.D.,
Philadelphia, Pennsylvania

WE did not have a clear understanding of the anatomy of the palate and particularly of the physiology of the muscles associated with the palate until we dissected the palate and structures associated with it. In fact we did not comprehend the abnormal physiology of the cleft palate until we had dissected a cleft palate specimen and studied the deficiency in the bony anatomy of the palate in clefts. Apparently no one else understood it until the explanation of how velopharyngeal closure is produced was brought out in the literature Wardill and Whillis, and Dorrance and Shirazy—all at about the same time—described how this function was performed. Hitherto it had been thought that in cleft palates the soft palate was grasped in some way by the superior constrictor muscle much the same as an obturator is grasped by the superior constrictor when a cleft exists.

Our anatomical studies show that closure is produced by the contraction of the superior constrictor muscle. Nowhere in the body that we know of is an orifice closed except by a complete circular muscle.

Material from America: Otolaryngic Hospital and Doctors Hospital, Philadelphia.

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1925.

Fig. 1. a, left Superior constrictor before contraction. Opening between nose and pharynx open. b, Superior constrictor in contraction. Opening between nose and pharynx closed.

The action of this so-called superior constrictor muscle is peculiar in that there is a compound action. If you will refer to Figure 1, a, you will get a more graphic conception of this muscle. The superior constrictor in the posterior pharynx is one muscle, having attachments on either side. As it comes forward one part goes to attach to the hamular and pterygoid processes the other splits off and is medially attached to the soft palate, extending so far medially that the fibers interlace with fibers of the opposite side. Figure 1, b shows these muscles in contraction—that is the superior constrictor has within its grasp the salpingopharyngeus muscle as well as part of the levator palatini. This perhaps is better shown in Figure 2. Here you can note that the palate is fixed to the posterior nasal spine and posterior border of the bony palate. If this is so then there can be practically no retroposition of the normal or cleft palate and its attachments during normal speech. If Figures 2 and 3 are studied it will be noted that when the fibers on the outer edge of the superior constrictor muscle which are attached to the hamular process contract, they draw the posterior wall of the pharynx forward. In this way they put the inner portion or circular fibers of the superior constrictor in position so that, when they contract, they produce velopharyngeal closure. As previously stated it is not possible to pull the palate backward because the superior constrictor muscles and the tensor palatine muscles are inserted into the palatine fascia, which in turn is inserted into the posterior border of the hard palate and to the posterior nasal spine. Now after the repaired cleft soft palate has been displaced backward to its normal position then this inner muscle which is marked on Figure 2 as the palatine fibers of the superior constrictor acts as a circular muscle and produces the closure. This is the

Fig. 2. Superior constrictor muscle at rest

Fig. 3. Superior constrictor muscle in contraction.

Fig. 4. Normal bony palate showing posterior nasal spine.

Fig. 5. Bony palate in cleft of the hard and part of the soft palate.

Fig. 6 a, left Note size of opening before push-back. b, Note size of opening after push-back.

normal physiological action for closing off the nose from the pharynx.

To recapitulate This physiological closure of the nose from the mouth was not understood by us until these studies were made. The normal closure is caused by the contraction of the outer fibers of the superior constrictor muscle which runs to the hamular process on either side pulling the posterior wall of the pharynx forward thus permitting

the inner portion of the superior constrictor muscle to act as a sphincter and produce closure. This anatomical physiological development was worked out by Dorrance and Shurazy (Figures 2 and 3).

If one knows the normal anatomy and then looks at a skull or better a dissection of a cleft palate case as shown in Figures 4 and 5 one will note that in the normal palate there is a posterior nasal spine and that the palatine

Fig. 7 N to size of the tensor palatine muscle.

aponeurosis is inserted into this area, as shown in Figure 4. In Figure 5 in which there is a partial loss of the hard palate it will be noted that the palatine aponeurosis is inserted along the margin of the cleft palate and if Figure 6 a, is studied it will be noted that the space back of the palate is so great in diameter that the anterior ends of the inner portion of the superior constrictor can not close this opening because the palatine aponeurosis has been drawn too far forward into the cleft. This Figure 6 a and b illustrates a point that we particularly want to bring out. If the palate is retrodisplaced so that the portion of the palate which was normally attached to the spine is now put in the position where it would be if the spine were present then the outer portion of the superior constrictor muscle can draw the posterior wall of the palate forward thus allowing the circular portion of the superior constrictor to produce closure.

A study of Figure 4 shows the normal posterior nasal spine. Figure 5 shows the point at the apex of the defective bone. It can be easily understood how that portion of the aponeurosis which is normally attached to the spine is now pulled forward and attached along either border of the defect. In this position if the two edges of the cleft were sutured together there would be an extremely long space for the circular muscle to close whereas, if you take the aponeurosis from each side of the bony cleft and retrodisplace it so that it would be where the normal spine should

Fig. 8. a, Represents normal pull of tensor palatine muscle. b After division of the hamular process, muscle becomes an elevator.

be then you put the circular portion of the superior constrictor in a position to produce closure. This really is the physiology of the push back operation.

It is well known that suturing together the two sides of a cleft palate as in a Langenbeck operation usually does not produce normal speech yet if you take these patients and retrodisplace the palate so that the attachment of the palatine aponeurosis is displaced backward the circular muscle portion of the superior constrictor is capable of obtaining velopharyngeal closure and normal speech ensues.

Fig. 9.

Fig. 10.

Fig. Not pull of levator palati before push back.

Fig. Not pull of muscles after push-back.

Recognition of the existence of this anatomical defect automatically excludes the use of the turn-over flap operations, such as those advocated by Lane

In clubfoot it is pretty well known that in certain cases there is a shortening of the tendons so that they must either be divided or lengthened before one can overcome the deformity. Well, a somewhat similar condition exists in the palate where the tensor palatine muscle due to the cleft, is shortened

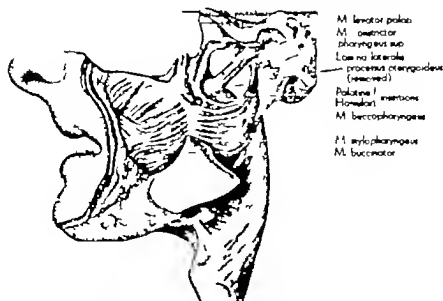

Fig. 3. Note insertion of palatine and hamular process.

Fig 14. Note two divisions of the superior constrictor one going to the hamular one going to the palate

Surgeons wondered for many years why a hole developed in the middle of the palate following operations. If for one moment you would examine a cadaver and see this extremely large muscle, the tensor palatine (most of us are inclined to think of it as a little muscle) it would be easily understandable why such separation occurs especially when there is a considerable pull (See Figure 7). For instance when a child is under an anesthetic these palatine muscles are stretched to get approximation of the palate then when the child comes out of the anesthetic this shortened muscle which has been abnormally drawn over into the midline becomes active and naturally there is a pull on the suture line which may give way and a hole results. In our push back operations, we relieve this tension by dividing the hamular process as recommended by Whitehead or if you prefer

by dividing the tensor palatine muscle as recommended by Pollock. In this way you eliminate a big factor causing the failure of the sutures to hold. This pull of the tensor palatine muscle was mentioned as early as 1846 by Liston. We have seen no harm from dividing the muscle but think better of dividing the hamular process (Figure 8) which makes the tensor palatine muscle become an elevator instead of an abductor—that is instead of being two sides of a right angled triangle it now becomes the hypotenuse.

These anatomical studies long ago proved to us that in cleft palate cases each type is different. The main objective is to return the aponeurosis which is normally attached to the posterior nasal spine to its normal position then closure is possible and normal speech becomes possible. As previously stated the reason for defective cleft palate speech is

Fig. 5 Cleft palate splint with packing in place.

operation is that the speech mechanism is defective with this retroposition of the tissues to their normal position we are now able to give the child a normal speech mechanism with which he may articulate properly. In other words, if you don't have a good speech mechanism you can't expect good speech.

This in turn brings up a fact which we think should be strongly emphasized and which after many years of experience in this type of surgery we feel is correct. It is this in the average case you have only one chance to produce a perfect palate therefore, extreme care and study should be given to the case. We have long since realized that early operations are not at all essential—in fact, failure in cleft palate repair in very young children is so common that now we do not advise operative work being done on a child until about the fourth or fifth year. We formerly had many partial failures and complete failures, whereas now that we are doing the operations later we are having fewer failures. Nowhere else in surgery is the value of delayed

flaps so essential for if you lose a flap you have difficulty in finding other material to take its place. We frequently raise flaps and suture them back, and then wait several weeks or months before completing the flap transfer. We are not unmindful of the advice given by others that the earlier these patients are operated upon the better the speech will be. We know that this is not true and yet many surgeons say "If only I had operated on the patient earlier I then could have gotten a better result." This in our opinion is erroneous. Our feeling at present is that the most favorable time to operate is from the fourth to the sixth year. We find that the speech in our average case is better than when we operated earlier. In our experience there are less anatomical failures, less loss of flaps, and speech is much superior to that which was obtained with the earlier operation.

In the past, the mortality rate of cleft palate operations was high. It still is higher than it should be. It can be definitely stated that the mortality rate is lower at the fourth year than at the first year and the speech is better when the operation is delayed. We can see no justification for a hurry up operation the statement that the case should be operated on early and that, if it is not operated on before the time for the development of speech, the child will never develop normal speech is not true—in fact the reverse is nearer the truth.

We take it for granted that some form of push back is essential in almost every palate case. We know that it is the only operation that is of value in cases of congenitally short palates. We know that in clefts of the soft palate it gives extremely satisfactory results. That leaves cases of complete clefts, unilateral or bilateral, to be considered. These, again must be divided into those that have a vomer attached to one side of the cleft and those that do not have a well developed vomer. In those that have the vomer attached we use our own vomer flap operation, as illustrated in Figures 9 and 10.

In our anatomical descriptions, we would like to show you Figures 11 and 12 which illustrate very definitely the change in insertion and pull of the palatine muscles,

before and after their retrodisplacement. We are now able by our push back operation to obtain good speech for those cases which had been repaired by the von Langenbeck method where velo-pharyngeal closure was not obtained. In these cases we are using a modified push-back in which we first raise the flap and cover the raw surface with a skin graft so as to produce a freely movable palate. We think the skin graft prevents scar and contracture.

Sometimes we have a hole remaining in the anterior part of the mouth. If this does occur it gives us very little concern, as a plate will cover it without much difficulty (Figures 13 and 14).

Figure 13 illustrates by a photograph of the dissection how the superior constrictor muscle goes into the hamular process and its circular portion swings around the levator palatine. Figure 14 shows the superior constrictor one portion going to the hamular process and the other portion going over to the palate. It also shows the large size of the tensor palatine muscle.

We would like to add that in all cleft palate operations where teeth are present, we are now using a splint as a means of protecting the suture line. This is true in vomer surgery as in any other surgery of the palate (see Figure 15).

GRADUATE TRAINING IN SURGERY

CHARLES R. REYNOLDS M.D. Major General U.S. Army (Retired) Chicago, Illinois

DISCUSSIONS of graduate training in general surgery and the surgical specialties at the Clinical Congress at Cleveland centered chiefly in two aspects. One was the development of additional programs of residency training to meet the present extraordinary requirements. The other was the importance of the medical school in graduate training particularly the methods of incorporating the basic medical sciences into training programs.

In tracing the progress made in the manner of treating the basic medical sciences since even the more recent prewar years, several important tendencies are evident. Among these are greater emphasis on the basic sciences other than anatomy and pathology which include biochemistry physiology bacteriology and pharmacology and upon clinical rather than didactic teaching. The review courses have given way to the study of these more or less exact sciences as they bear directly on clinical procedures. The necessity of adequate knowledge of the applied basic medical sciences being established, the problem shifts to the hospitals in which the training programs are prepared and carried on. Frequently this calls for co-operation between the hospital and the medical school.

A panel discussion of graduate training in general surgery and the surgical specialties from the standpoint of the American College of Surgeons, the university-connected hospital the hospital not connected with a university the Veterans Administration hospitals and the graduate medical school, being open to hospital representatives as well as surgeons, developed free exchange of ideas by practically all agencies involved.

Representatives of the Department of Graduate Training in Surgery of the American College of Surgeons described the existing situation as to approved residencies and the work of the College in assisting hospitals possessing potentialities to develop graduate

training programs and those hospitals now conducting residency programs of 2 years duration to rearrange them to conform with present requirements as to content and duration. The interest of residents now receiving training of inadequate scope was emphasized. The benefits accruing to hospitals by modernizing their programs were described. They can by so doing maintain their status as modern teaching institutions and will be enabled to meet the situation when the wartime supply of residents will have become exhausted and hospitals may then be on the lookout for residents instead of the reverse order of today. Internes of the future will be looking for residencies which meet the requirements of accrediting agencies.

Having in mind the probability that more hospitals might be brought into the sphere of graduate training in surgery if assistance of medical schools were made available, a member of the staff of the Department of Graduate Training in Surgery has visited more than fifty medical schools throughout the United States and Canada. He developed interest in collaborative programs and discussed at each medical school particular problems. Surveys were made of hospitals offering the best opportunities for development of co-operative programs in order to ascertain the amount and character of assistance required by each. As a result of these efforts it has been possible in many places for the medical school to become the center of a collaborative regional effort.

At the present time thirty medical schools are offering varying types of assistance in co-operative graduate training. Others are preparing to do so. Such assistance will not only increase the number of approved programs but will tend to improve the quality of training in many programs which have already been approved by bringing the hospital permanently into the sphere of influence of the medical school.

The university-connected hospitals are situated more fortunately than any others in availing themselves of medical school re-

sources. The methods of supplying this need which centers chiefly around the basic medical sciences have changed recently because of the added burden falling upon medical schools. Some schools formerly carried on this training by distributing its component parts to the undergraduate departments. Recently the tendency has been to develop a comprehensive course in the applied basic medical sciences and closely allied clinical training under central authority. By this means uniformity of training is insured and can be made available to larger numbers of trainees including those from affiliated hospitals. These courses have been lengthened from several months to as much as nine months because of this added requirement coming especially from returning medical veterans. Perhaps a more difficult problem is to supply the more or less limited or special needs of residents in hospitals capable of providing the other elements of the residency program. Chief among these is surgical anatomy. In such instances no procedures of universal application are possible. Recourse to the preclinical department of the medical school is often necessary but with the necessity of practical teaching ever in mind.

It is the consensus that the graduate medical school course, usually of eight or nine months duration, provides the most satisfactory training in the applied basic medical sciences and allied principles of surgical technique as the basis for continued study and work connected with this important feature of surgery throughout the years of residency. Just when an academic year at a graduate school is most advisable has not been generally agreed upon. Graduate schools are furnishing some of their graduates to hospitals. Others are receiving residents who have completed part of their training usually the first year.

Opening the field of graduate training to such smaller hospitals as are found capable of making a contribution of a supplementary nature to training programs centering in larger institutions will broaden the training and supply missing elements in programs particularly in the surgical specialties. This is exemplified by some children's hospitals which can provide one year of training in children's ortho-

pedic surgery needed to round out the program confined largely to adult orthopedic surgery and fractures in another hospital. This project had occupied the attention for several years of the Joint Committee of the American Orthopedic Association and the American Academy of Orthopedic Surgeons and the American College of Surgeons has formally approved a number of such programs as well as others in pediatric surgery under similar circumstances.

The educational policies of the newly established Medical Department of the Veterans Administration emphasize a trend in medical education which will be of great importance in years to come. The basic feature is the close association of Veterans Hospitals with nearby medical schools whose faculties have been drawn upon to improve professional service and to supervise or conduct training programs substantially meeting the fundamental requirements of the American College of Surgeons. Today fifty seven medical schools are working through their Deans committees with fifty two Veterans Hospitals. Consultants from the faculties of these schools and associate attendings have contributed to the establishment of a system of residency training that has won the admiration of the profession. About 1500 medical veterans are now receiving graduate training in these hospitals. This is relieving a serious situation confronting medical veterans in need of training at a time when civilian hospitals are overtaxed. The expected mass hospitalization of veterans may be utilized eventually in graduate training on a correspondingly large scale.

Virtually the same principles are being put into effect in the graduate educational procedures of the Army, Naval and Public Health services and as already noted these policies are spreading to all communities where such cooperation is found practicable. The improvement in the care of veterans and assurance of the continued association of highly trained consultants under an improved system of hospitalization means that there will be a continuation of the high esteem in which the public now holds the medical profession for the unprecedented service which it provided during World War II.

GENERAL REVIEW 1946 CLINICAL CONGRESS

MALCOLM T MacEACHERN M D Chicago, Illinois

THE Clinical Congress in Cleveland was an event that adds another bright memory to the record of successful episodes in the history of the American College of Surgeons. Meeting rooms overflowed interest ran high and the education of the surgeon was advanced through the presentation of talks, clinics, demonstrations, and discussions covering developments that have occurred in the five years since the last Congress was held. Neither the time—the week before Christmas—nor the postponement from the September dates originally planned for the Congress in New York—were deterrents to the surgeons who wished to take advantage of the opportunities for learning about new ideas and techniques.

The Committee on Local Arrangements, of which Dr. Thomas E. Jones was Chairman is to be highly commended for its help in arranging the excellent clinical program which was developed in the local hospitals, and for its many other activities in connection with the planning and conduct of the Clinical Congress.

The setting in the Cleveland Public Auditorium made the Congress quite different from preceding meetings, usually held in hotels. Arrangements for display of exhibits in the Arena were ideal and meeting rooms were ample in number and with a few exceptions sufficiently large to accommodate the audiences. Two of the noteworthy exceptions were the symposia on Fractures and on Cancer attendance at which overflowed the capacious fourth floor Ballroom. The experience demonstrated the desirability of again giving great emphasis to these two subjects in the 1947 Congress.

It is customary to select a dominant note about which to focus the impressions of any meeting. In connection with the Cleveland Congress, that is hard to do. There were many subjects concerning which interest was especially keen. Doubtless developments in the field of cancer attracted the most notice, al-

though since cancer is a disease which attacks any part of the body discussion of its treatment consequently comes up in meetings devoted to almost any specialty.

Since this special issue of SURGERY Gynecology and OBSTETRICS carries most of the papers which were presented at the more formal scientific sessions, it will be unnecessary here to mention their content. It would be very advantageous if in addition we could present summaries of the excellent panel discussions which were held but this is not practical mainly because of lack of space.

The forums on Fundamental Surgical Problems have won an established place of great importance on the Clinical Congress program. It would be impossible to overestimate their value as an incentive to the younger surgeons and an avenue for the reporting of the results of the latest research. A few of the presentations are published in this issue.

The sessions of the Hospital Standardization Conference were interesting and stimulating. The meetings were successful in giving opportunities for helpful discussion of the many pressing problems that must be met in hospitals today. Nursing service naturally occupied a foremost place among the subjects listed, and solutions to the problem of short ages were presented in suggestions to improve personnel policies, to stimulate recruitment of student nurses, and to train a secondary group to assist the graduate nurse. The improvement of medical records, the education of the hospital trustee, the responsibility of the administrative staff in handling emergencies coming to the hospital and occurring within it, and the training of hospital personnel were other subjects to which entire sessions were devoted.

A preliminary summary of the 1946 Hospital Standardization report was presented by Dr. Irvin Abell, Chairman of the Board of Regents, at the opening General Assembly. The report showed 3,118 hospitals approved—79.3 per cent of the 3,934 which were under survey during the year.

SURGERY

GYNECOLOGY AND OBSTETRICS

VOLUME 84

MAY 1947

NUMBER 5

TREATMENT OF TRICHOMONAS VAGINALIS VAGINITIS

WALTER J REICH MD FACS HELEN L BUTTON MD and
MITCHELL J NECHTOW MD Chicago, Illinois

THE treatment of *Trichomonas vaginalis* vaginitis was approached for the investigation here reported as a problem involving (1) the effectiveness of the therapeutic agent under test and (2) the effectiveness of the steps taken against recurrence.

The work was done in the outpatient gynecological clinic at Cook County Hospital Chicago and in the private practice of the investigators participating 2080 patients were examined for presence of *Trichomonas vaginalis* infection 541 were found to be positive 205 were available for study and 153 were followed with sufficient completeness for report.

PROCEDURE AND RESULTS

Differential diagnosis and examination A history was taken and a preliminary examination made of the vulva with particular attention to the character amount, color and odor of the discharge

Irritation and itching usually were complained of in association with a leucorrhoea and pruritis bladder indications of frequency and urgency often were present and occasionally dyspareunia vaginospasm and sensation of heaviness

Examination of the vulva revealed skin manifestations of infection ranging from normal skin to extensive vulvitis (Figs. 1 and 2

insert) Perirectal irritations and occasionally accompanying condylomata acuminata were found The common finding was that of an inflamed mucous membrane with pinpoint petechiae dispersed over the cervix Examination of Skene's glands and the openings of the Bartholin glands showed evidence of infection in more than 50 per cent of the strongly positive trichomonas cases Cervicitis endocervicitis with erosions polyps and nabothian cysts frequently were found as incidental pathology Tender indurated sacrouterine ligaments were found in approximately 5 per cent of the apparently acute strongly positive cases

Unlubricated speculums were used for the vaginal examination After noting all pathology pH determinations were made with nitrazine paper Next the type of vaginitis was identified through microscopic examination of a hanging drop of vaginal secretion and frequently an undiluted wet smear and Gram stain

The specimen for microscopic examination was prepared by releasing onto a drop of normal saline on the cover slip a drop of secretion obtained from the posterior fornix by means of an 8 inch glass tube tapered at the sampling end and with a rubber bulb to provide suction at the other

The number of trichomonads was counted under high power magnification A field containing only an occasional trichomonad or less than 3 was classified as + A field con

From the Gynecological Division of the Fantus Clinics, the Cook County Graduate School of Medicine and the Hektoen Institute for Medical Research Cook County Hospital.

Treatment of Trichomonas vaginalis Vaginitis—
 Walter J. Reich, Helen L. Sutton and Mitchell J. Nechtow

taminated tub, pool toilet seat, linens or sexual congress may provide a reasonably safe means of protection.

The possibility of the male as a source of infection has been forcefully emphasized by Feo (4) who states that 'the male is not only responsible for the reinfection of women but is the principal agent of transmission. Allison terms trichomoniasis the 'seventh venereal disease. Proper feminine hygiene measures should be taken particularly where reinfection is suspected and later proved to have come from the marital partner.'

Safety. The instruction to return for re-examination at the end of each consecutive week of treatment permitted close observation of progress and also at the beginning of the study, the very necessary assurance that the treatment was altogether safe for continued use. No indication of harmful effect was found

Dr J. Lester Wilkey of the Genito-Urinary Department of Cook County Hospital, Chicago, has observed (personal communication) in a series of 6 instances of *Trichomonas vaginalis* infection in the male, the presence of urethral strictures derived from an earlier gonorrheal infection, and suggests that such strictures may act as dams behind which trichomonads may be harbored. The treatment given consisted of prostatic massage with urethral dilatation once weekly followed by anterior-posterior insufflation of .5 per cent solution of mild silver proteus, with precaution against reinfection. A 5 per cent solution of mild silver proteus was prescribed for latent urethral infection by the patient twice daily.

Fig 3 Insufflation of argyrol compound powder front view

at any time and no instance of sensitivity to type or method of treatment. No argyria was seen. (Long continued use of any silver preparation carries with it a risk of argyria and should be avoided. A search through the published records up to 1939 by Hill and Pillsbury found record of no

Fig 4 Insufflation of argyrol compound powder lateral view

Fig 5 Composite drawing showing possible sources of reinfection

instance of generalized argyria associated with the use of mild silver protein as the only form of silver given, in the genitourinary region but did find report of one instance following a combined use of mild and strong silver protein as a urethral irrigation. The duration of use was reported to have been 6 weeks.)

Re-examination and continuation of treatment
Few of the patients adhered, without lapse to the schedule of return for re-examination and continuation of treatment that was requested of them. This schedule required in the absence of recurrence a total of 8 reports to the clinic weekly during the month of treatment at 3 week intervals during the next $2\frac{1}{4}$ months and again 3 months later. Treatment was not interrupted during the menstrual period.

Following each re-examination during the period of treatment, an additional insufflation

was given and 6 additional capsules, for use as before with instructions to return again for examination at the end of the week, etc.

As is reported in Table I the infections with an initial classification of +++ or ++++ required longer treatment on the average than those with an initial classification of + or ++ and had a greater tendency to recur. The number of weeks of treatment given in the absence of recurrence was between 3 and 4 and in the presence of 1 or at most 2 recurrences, between 5 and 7. The percentage of patients successfully treated was 98.

The outcome in the unsuccessfully treated patients, was one suggesting failure, not on the part of the therapeutic agent but of the precaution against reinfection (Fig 5).

Results approximately equivalent to those obtained by the combined use of insufflation and capsule insertion were observed following

Fig. 6. Comparative bacteriostatic power of the argyrol kaolin, lactose powder against gram-positive *Staphylococcus aureus*, A and *Streptococcus pyogenes*, B, and gram-negative *Escherichia communior* C, *Pseudomonas aeruginosa*, D, and *Eberthella typhosa*, E. Tests made by a modification of the agar streak plate dilution method described by Waksman and Kelly.

Agar plates containing: I no argyrol, kaolin, lactose powder; II the powder in a dilution of 1:5000 and, III in a dilution of 1:500. Note the complete restraint of growth at 1:500 and the marked restraint even at 1:5000.

the use of capsules alone. However, the return of the patient for insufflation provides for an automaticity of re-examination and control not possible through the use of capsules alone.

A study was made by one of us (M J N) of the rate of disintegration and dispersion of the capsule following its placement high in the vaginal vault. Hourly observations were made and the process was found to be rapid, resulting in an apparently uniform distribution of the contents throughout the vagina within 3 to 4 hours.

MODE OF ACTION

The action of the powder would appear to be of the type exerted by the sulfonamides and by penicillin against the infections for which they are most effective—a mild, checking action, gradually depriving the pathogen of its foothold. Mild silver protein has been demonstrated to exert an additional germicidal effect but that effect is secondary in importance to the checking effect imposed. A direct killing of *Trichomonas vaginalis* by 0.5 per cent mild silver protein *in vitro* has been observed by Shelanski which was reported to be complete in 8½ minutes. Morgan and Campbell observed a similar effect by 1 per cent mild silver protein versus *Trichomonas foetus*. Buca found mild silver protein to be lethal for the gonococcus in a dilution of 1:50,000.

The photographs in Figure 6 indicate graphically the extent to which mild silver protein-kaolin-lactose powder checks the

growth of representative gram positive and gram negative bacteria. There would seem to be little question of its capacity to control either *Trichomonas vaginalis* or the disturbed bacterial flora associated with it in the production of *Trichomonas vaginalis* vaginitis.

DISCUSSION

In our clinic, we have tried and had experience with all of the classical approaches to the treatment of *Trichomonas vaginalis* vaginitis.

TABLE 1.—DURATION OF TREATMENT IN RELATION TO INITIAL CLASSIFICATION AND FREEDOM FROM SOURCES OF RECURRENCE

Group	Initial classification	Number of recurrences	Number of cases	Average total no. of weeks of treatment	Per cent of group responding successfully to treatment

		multiple		—*	
	Combined		69		

† Not responding effectively. Indication for further search for source of recurrence rather than extension of treatment.

Series A, clinic patients; Series B, office patients, studied over the same period.

Cleansing the external genitalia with tincture of green soap and warm water with drying of the vaginal tract followed by treatment with a stream of warm air has proved to be time-consuming and cumbersome with fractional results even though trichomonadocidal agents were applied following the procedure and prescribed nightly for the patient. The substances used for this purpose were picric acid (1 per cent) methylene blue (1 per cent) gentian violet (2 to 5 per cent) and saturated solutions of sodium perborate.

Various types of insufflation powders were explored containing pentavalent arsenicals or silver picrate. Supplementary to the use of these preparations in the clinic the patient nightly at home used the same drugs in tablet or suppository form. An acid douche usually vinegar was also prescribed twice a day mornings and afternoons along with the clinic and home medication. Quinine sulfate oxyquinoline sulfate and the lactic acid oxyquinoline jellies also were given thorough trial.

Fairly good results followed from the use of all these procedures with however failures which led to a review of basic principles and the development of the method of approach described.

Work of others. A thorough review of the background of the problem appears in the report of the American Medical Association Council on Pharmacy and Chemistry on status of treatment of *Trichomonas vaginalis* vaginitis (10). Authoritative conclusions on the pathogenicity of *Trichomonas vaginalis*

have been brought forward by Trussell and Plass, Hesselstine and Feo Rakoff and Stabler (5). Comprehensive information on incidence is given by Peterson.

SUMMARY

A combined use of mild silver protein, kaolin and beta lactose in powder and vaginal capsule together with search for and elimination of foci and sources of reinfection gave a successful result against *Trichomonas vaginalis* vaginitis in 97.6 per cent of a group of 84 negro patients and 98.6 per cent of a group of 69 white patients studied under both clinic and office conditions and with infections varying in initial severity and extent over the usually encountered range.

EXTENSIVE HEMANGIOMA

Report of Cases

DANIEL C ELKIN M.D. F.A.C.S. and FREDERICK W COOPER Jr M.D.
Atlanta Georgia

REPORTS appear in the literature of extensive hemangiomas for which multiple or radical operations have been performed for their cure. Since the lesion although rarely malignant progressively enlarges, the necessity for its removal is apparent. Many methods of therapy have been instituted, but only in those instances which result in the total eradication of the lesion can one hope for permanent success. At the onset these lesions may produce only cosmetic deformities but eventually functional impairment and pain will result. Hemorrhage, malignant degeneration and progression to true cirsoid aneurysms are further indications for radical extirpation.

PATHOLOGY

Hemangiomas are tumors of independently growing blood channels which probably have their origin as embryonic rudiments of mesodermal tissue. The concept that they result

From the Vascular Surgery Center, Ashford General Hospital, White Sulphur Springs, West Virginia and the Department of Surgery, Emory University.

from dilatation of blood vessels or organization of hemorrhage has long been discarded (5, 7).

Classification is usually of two types: cavernous hemangioma, and capillary hemangioma. The point of division between the two types is frequently difficult unless the specimen is carefully examined before fixation. Watson and McCarthy have classified them into eight groups: (1) capillary hemangioma, (2) cavernous hemangioma, (3) angiohistiocytic or hypertrophic hemangioma, (4) racemose hemangioma, (5) diffuse systemic hemangioma, (6) metastasizing hemangioma, (7) nevus venosus or port wine stain and (8) hereditary hemorrhagic telangiectasis.

The microscopic picture is one of endothelial spaces of varying size surrounded by interstitial connective tissue (Fig. 1). The amount of lipid and fibrous tissue varies markedly; the proportion of these elements will determine the compressibility and consistency of the mass (Fig. 2). Many of them have the appearance of lipoma. It may be well encapsulated, occupying a position between muscle

Fig. 1 Photomicrograph of a typical cavernous hemangioma.

Fig. 2 Photomicrograph of a hemangioma with large amount of connective tissue and small vascular channels.

Fig. 7 a, left, Hemangioma of forearm with rapid growth. b Result after excision

Following trauma or thrombosis of a major venous channel leading from the tumor rapid enlargement may occur. The tumor then may become painful and simulate an acute inflammatory process.

Due to the variation in consistency and compressibility of the mass other conditions such as large dilated varices, lymphangiomas, and lipomas are to be differentiated from it. The deposition of fat about the vascular channels may be so great as to give the tumor the appearance of a lipoma even at the time of operation. In occasional instances the expansile quality may be absent. The true nature of the tumor is then appreciated only if it is incised exposing the vascular spaces. A lymphangioma may be compressible but is reduced in size less readily and expands less rapidly when released. Large masses of var-

ices confined to a single area are differentiated by the greater ease with which they are emptied on compression and by the tests for varicose veins.

TREATMENT

Complete removal of the tumor is the ideal treatment. This is not always possible, for in lesions about the head loss of facial expression may result from associated injury to the facial nerve. Extensive removal of muscles about an extremity may destroy the function of the part, and at times the major nerves are so intimately involved in the process that removal of the tumor without injuring them is not possible. It is believed that in so far as it is compatible with essential functions of the individual every attempt should be made completely to excise the lesion for these tumors increase steadily in size and frequently undergo changes of distressing or even fatal nature.

Excision. All cases in this series were treated by excision. The overlying skin was excised if it was involved and if a satisfactory closure could not be obtained skin grafting was done.

Irradiation was employed only in instances in which surgical excision was inadvisable or incomplete after exploration of the lesion. The use of sclerosing solutions would seem futile in large cavernous tumors and such treatment was not employed.

Review of cases (Table I). In the cases reported in this series all patients were treated by surgical excision. Many other hemangiomas were seen but those of small size and

Fig. 8 a, left, Hemangioma of hand with involvement of intrinsic musculature median and ulnar nerves. b, Postoperative result after excision of portion of the mass.

Fig. 9 a, left, Hemangioma of parotid region and temporal muscle with expansion as head is depressed. b Photograph following partial excision of the tumor

involving only the skin are not included. Other instances of port wine blemishes involving large areas were not excised. Tumors of the parotid region except for 1 instance in which it was believed that the mass was superficial were uniformly referred for irradiation therapy.

History of trauma was present in 14 cases. It is believed that trauma is frequently the

factor initiating increased growth in an underlying congenital lesion.

Pulsation was present in 3 instances and in 2 of these a bruit was audible and was interpreted as evidence of large arteriovenous communications.

In 1 instance the median and ulnar nerves were infiltrated making excision impossible without removing the nerves.

13	Thigh												
14	Cheek									?			
15	Forehead												
—	Total		14							14-1	6		7

In 12 instances the tumor was completely excised. In 7 the mass was removed but a small amount was left. 1 case involved the masseter muscle alone and although this muscle was removed the complete extirpation of the origin of the muscle was not confirmed. All muscles of the shoulder girdle were infiltrated in 1 instance and the tumor could not be removed without sacrificing the arm. In 2 instances the masseter and temporal muscles were involved and left after excision of the major portion of the mass. The remainder of the failures were associated with extensive port wine blemishes in which the expansile portion of the tumor was removed but in which it was not felt justifiable to do widespread skin excision. Postoperative irradiation therapy was employed in 3 patients.

SUMMARY AND CONCLUSIONS

1. Nineteen cases of extensive hemangiomas treated by surgical excision are reported.

2. The preoperative evaluation of the probability of complete removal is difficult because of the fact that the tumors are deceptive as to extent and involvement of adjacent structures.

3. Cures were effected in 63 per cent of cases and improvement obtained in the remaining 37 per cent.

THE CHOICE OF OPERATION FOR THE TREATMENT OF ARTERIOVENOUS FISTULAS

E. CRAIG HERINGMAN M D New Orleans, Louisiana

QUADRUPLE ligation with excision of the fistula has been the classical operation in the treatment of arteriovenous aneurysm for many years. Holman, Herrmann and Reid and Elkin have advocated this procedure as being the most useful and effective technique. Recently however reports have appeared which indicate that although patients treated in this manner may not develop gangrene after operation nevertheless a good many of them will show evidence of chronic vascular insufficiency distal to the ligated vessels. Symptoms such as intermittent claudication, ischemic pain, numbness, tingling, atrophy of muscles, or coldness of the skin may develop to plague the patient even though a successful quadruple ligation has been accomplished. Mayberry, Bigger and Freeman all have stressed that these untoward postoperative conditions may be avoided by closure of the fistula and repair of the artery. In a recent report, Heringman, Rives, and Davis studied 53 cases of arteriovenous fistula for evidence of postoperative vascular insufficiency. It was found that there was no instance of vascular inadequacy following transvenous arteriorrhaphy as compared to an incidence of 27.5 per cent following quadruple or sextuple ligation and an incidence of 71 per cent following obliterative endoaneurysmorrhaphy. It was stressed that restoration of normal arterial circulation is the primary objective of the surgeon whenever possible.

Unfortunately there exist at the time of operation many complicating conditions which may prevent the repair of the artery. Therefore one must resort all too frequently to quadruple ligation or at times to obliterative endoaneurysmorrhaphy in order to eliminate the fistula. It is the purpose of this paper to discuss those factors which are the basis for

the choice of operation in a patient with arteriovenous fistula. Although these factors are known to the vascular surgeon, relatively little has been said about them in recent discussions and it is considered worthwhile to re-emphasize their importance. Certain appropriate cases taken from the group of 53 analyzed in the original paper (7) are used as examples to illustrate how these factors influence the choice of operation.

OPERATIVE PROCEDURES

In general there are three main types of operative technique available to the surgeon when dealing with an arteriovenous aneurysm. The first and most frequently used is a ligation procedure, either quadruple or sextuple ligation with excision. The second is a restorative procedure utilizing some method of arteriorrhaphy or a technique requiring the use of vitallium tubes with a venous graft (3). The third is an obliterative procedure, the intrasacicular endoaneurysmorrhaphy advocated by Matas (10).

The advantages and disadvantages of these procedures merit a brief discussion.

LIGATION PROCEDURES

Quadruple ligation with excision. The advantages of this operation are derived from the fact that when properly performed it is a relatively safe procedure and effectively eliminates the fistula without causing gangrene. It is frequently the operation to which one must resort if a restorative procedure cannot be done. However there are certain definite disadvantages inherent in this operation.

1. It requires ligation of the main arterial pathway which should not be done unless it is absolutely necessary.

2. Dissection around the sac necessitates ligation of some collaterals which may be essential for maintenance of blood flow to distal parts.

From the Department of Surgery, Louisiana State University School of Medicine.

3 The dissection of the sac is often time consuming requiring the ligation of innumerable bleeding points caused by increased pressure in the veins around the fistula

4 It is not physiological

5 It is followed in many cases by evidence of postoperative vascular insufficiency

Sextuple ligation This is a procedure required for an arteriovenous fistula which occurs between an artery and its two venae comitantes. It is fundamentally a ligation and excision operation with disadvantages which theoretically do not differ from those mentioned under quadruple ligation and excision. However this technique is ordinarily the only one of advantage in the presence of dual fistulas.

RESTORATIVE PROCEDURES

Transvenous arteriorrhaphy (Matas-Bickham, 1) This procedure is performed without difficulty if the fistula occurs in a region where the blood supply can be controlled either by a proximal constrictor or by temporary ligatures on the artery and vein proximal and distal to the fistula

The advantages of this operation are well known

1 It preserves the main arterial pathway which is especially important in certain regions such as those supplied by the common carotid, internal carotid and popliteal arteries.

2 It provides a rapid approach to the fistula, which can then be closed under direct vision

3 There is minimal interference with the collaterals because little dissection is required around the fistula or the sac.

4 Patients who can be treated successfully by this method show little evidence of postoperative vascular insufficiency

Disadvantages inherent in this procedure stem chiefly from local contraindicating factors, which become apparent only at time of operation

1 It requires an arterial wall which has not undergone advanced pathologic change and has not become involved in dense scar tissue (The presence of such findings creates insurmountable technical difficulties.)

2 Sufficient normal arterial wall must be present in order to permit closure of the fistula without a serious reduction in the lumen of the artery

3 It requires control of circulation which at times may be difficult or impossible to obtain

4 Occasionally the repair of the artery will result in a marked reduction or even complete obliteration of the lumen. This is a technical error and every effort should be made to avoid it.

5 Should postoperative infection supervene, the suture line may give way causing serious secondary hemorrhage

6 Occasionally recurrence may follow restoration of the arterial pathway. This complication has been reported by Reid, Pemberion and Black, Bigger and Freeman

7 Thrombosis of the artery may occur at the site of repair

8 Unless the artery is exposed completely and carefully examined a weak point in the arterial wall may be overlooked which may result in the subsequent development of an aneurysm.

Transverse suture This technique has been advocated recently by Freeman. Since both artery and vein must be completely exposed to permit their detachment at the site of the fistula, there is little likelihood that a weakened area in the artery will be overlooked.

This complete exposure of artery and vein is an advantage over transvenous suture because with a direct approach to the fistula through the vein complete exposure of the vessels is not necessary and a pathologic area in the arterial wall can be easily overlooked. Another advantage of this procedure has been demonstrated by Freeman who used this method of repair successfully even though the wound may involve as much as three-fifths of the arterial wall. Such a wide defect obviously cannot be eliminated by the transvenous technique employing longitudinal suture without encroachment on the lumen of the artery

The disadvantages of this operation are essentially the same as those of transvenous arteriorrhaphy. Furthermore, a long slit like opening between artery and vein cannot be closed transversely

Fig. 1 a, left, Arteriogram taken of a patient of Dr. Urban Blas shows a large popliteal arterial aneurysm with the artery entering the upper pole. b Arteriogram of same patient following an obliterative endoaneurysmorrhaphy. Note two large branches which have been preserved despite their origin close to the sac. If ligation of the artery had been done, these collaterals undoubtedly would have been lost.

Vitallium tube venous graft method (Blake more and Lord) The development of this technique offers a new approach to the problem of restoring the artery to normal function. It seems advantageous for the following reasons:

- 1 It permits complete excision of the fistula, sac, and that portion of the artery which has undergone pathologic change.
- 2 Despite excision of the involved segment, the main artery is restored to function by means of a venous graft.
- 3 It is relatively simple and does not require suturing of blood vessels.
- 4 It is actually a combined quadruple ligation and restorative procedure thus presenting the advantages of both.

The disadvantages of the operation may arise from the fact that dissection of the sac and fistula may seriously interfere with collateral circulation. Because of this vascular insufficiency may result if early thrombosis should occur in the venous graft.

OBLITERATIVE PROCEDURES

Intrasaccular obliterative endoaneurysmorrhaphy designed primarily for the treatment of true or false aneurysms has also been used successfully in the treatment of arteriovenous

aneurysms. This operation requires adequate proximal control of circulation by a constrictor.

The advantages of this procedure are

- 1 It cures the fistula.
 - 2 It preserves the collaterals because no dissection is required around the sac. Figure 1 shows an example of how collaterals are preserved by this method.
 - 3 It is extremely useful in the presence of a large sac with numerous communications.
- The disadvantages of this procedure are
- 1 It obliterates the main arterial pathway.
 - 2 It can be done only in an area where proximal control of circulation by a constrictor is possible.
 - 3 It may be followed by a high incidence of vascular insufficiency.
 - 4 The lesion may recur if one of the openings in the sac is overlooked or if one of the suture lines breaks down.

CHOICE OF OPERATION

The decision as to what technique should be used is frequently difficult. Since no two cases are alike a number of complicating conditions present themselves at operation and require individual consideration.

The great variability of these factors prevents any attempt at rigid classification. However a satisfactory division can be made by grouping them under two main headings, depending on whether they are local or general in nature. The classification as presented in Table 1 indicates the more important factors.

TABLE 1 —FACTORS INFLUENCING THE CHOICE OF OPERATION

Local factors	General factors
Scarring around the vessels secondary to the original trauma.	Cardiac status of the patient.
Local pathologic changes in the walls of the involved vessels.	Presence of generalized arteriosclerosis.
Anatomic location of the fistula.	Occupation of the patient.
Factors relative to the aneurysmal sac	
a. Presence and location of the sac in relation to the fistula.	
b. Size of the sac.	
c. Condition of the sac wall.	
Collateral circulation.	

Local Factors

Scarring around the vessels secondary to the original trauma. Here the nature of the injury and the presence of coincident infection are important. If the walls of the vessels or of the sac are involved in dense scar tissue dissection is often hazardous and may produce severe hemorrhage. Matas (11) points out that repair of the artery is practicable only in recent injuries in which adhesions are not so dense as to prevent mobilization of the vessels. One of the cases in the series previously reported exemplifies the difficulties that may occur because of dense scarring found at operation.

CASE 1. A. B. was admitted to Touro Infirmary in 1938 with an arteriovenous fistula of the left common femoral vessels resulting from a gunshot wound of the left groin incurred 11 years earlier. At operation a considerable amount of scarring was found involving the walls of the vessels as well as the surrounding tissue. Dissection of the vessels in the region was attempted but accidental opening was made into a large venous channel. The ensuing hemorrhage was so severe that the operation was discontinued and a pack placed in the wound for hemostasis. About 10 days later ligation of the external iliac vessels was performed. After removal of

the pack from the original operative wound, severe infection developed causing profuse secondary hemorrhage, which was controlled with difficulty. The patient ran a markedly septic course for approximately one month and finally recovered. Fortunately evidence of the fistula disappeared and the patient was discharged from the infirmary with no further complications.

The choice of operation was determined by the local factors. The technique was an improvisation at best. Ligation of the external iliac vessels eventually produced a cure, but secondary infection, thrombosis, and thrombophlebitis probably were contributing factors in the disappearance of the fistula. This also serves to emphasize the importance of obtaining control of the proximal and distal circulation before dissection in the area of the fistula is begun. If temporary control of circulation can be achieved before the fistula is attacked directly unfortunate complications may be frequently avoided.

Presence of local changes in the wall of the involved vessels. This factor must be carefully determined before a decision can be made as to the proper procedure. When pathologic changes occur in the arterial wall, such as marked thinning and dilatation, calcification, or fibrosis, transvenous arteriorrhaphy may be dangerous. In such cases quadruple ligation and excision of the involved vessel segments with the fistula is the procedure of choice. This is exemplified in the following case.

CASE 2 (Fig. 2). A. M. was admitted to Touro Infirmary with an arteriovenous fistula of the popliteal vessels as a result of a gunshot wound incurred 3 months earlier. When the wound was explored considerable scarring was found and the wall of the artery opposite the fistula was thin and bulging. The fistula and the involved vessels were isolated by careful dissection and the lesion excised by means of a quadruple ligation. The patient suffered no untoward effects postoperatively.

Obviously arterial repair in this case would be hazardous because of the weakened arterial wall. Even if arteriorrhaphy could be accomplished the thinned area would remain as a possible site for early rupture with dangerous secondary hemorrhage or late aneurysmal dilatation.

The anatomic location of the fistula. The relationship between proximity of the fistula to the heart and subsequent development of car-

Fig. 2. Arterial wall opposite the site of fistula was thin and bulging. Quadruple ligation and excision of the fistula with the weakened portion of the artery was performed.

diac changes is too well known to merit more than a passing reference. Management of the local lesion, however, will vary according to the vessels involved. For example, a lesion of either one of the main arteries at the wrist can be treated by ligation and excision, because there is always an adequate secondary arterial circulation. This is also true of other regions where collateral circulation is known to be adequate.

On the other hand, lesions of large main vessels present a much more serious problem. The choice of operation for a fistula involving the common or the internal carotid artery requires careful judgment. Collateral circulation usually does not develop satisfactorily in such cases, and with a quadruple ligation or obliterative procedure there is always the risk of hemiparesis, especially in older individuals. This unfortunate complication can often be avoided by a procedure designed to restore the arterial pathway. Arteriorrhaphy, whenever possible, is always preferable in the presence of a fistula involving the common or internal carotid artery. The following case demonstrates the suggested method of handling such patients.

CASE 4. L. N. entered Charity Hospital with an arteriovenous fistula of the right common carotid artery and internal jugular vein, caused by a gunshot wound incurred 7 weeks prior to admission. Three weeks later a modified transvenous repair of the fistula was performed with reconstruction of the carotid artery and the ligation of the internal jugular vein above and below the fistula. Heparin was administered after operation and a hematoma developed rather promptly. This was evacuated and the

Fig. 3. Diagrammatic sketch of a modified transvenous arteriorrhaphy. In order to avoid tearing the internal jugular vein, complete liberation from surrounding scar tissue was not attempted. Instead large U mattress sutures were placed across the fistulous opening and tied. The vein was then interrupted above and below the fistula and the wall sutured to reinforce the closure of the fistula.

remainder of the postoperative course was uneventful. The patient was discharged fully recovered with no evidence of cerebral vascular deficiency. Figure 3 shows the lesion and the method of repair which was used.

Fistulas of other large vessels also merit a determined attempt at restoration of the arte-

Fig. 4. Transvenous arteriorrhaphy with section of vein proximal and distal to fistula.

Fig. 9. Blackmore-Lord technique utilizing a venous graft and two vitallium tubes.

If the collateral circulation in this patient had been found inadequate an obliterative endoaneurysmorrhaphy could have been done in an effort to preserve as many accessory vessels as possible. To avoid suturing through an area of calcification a disc of calcified sac wall is excised around each opening. This will ordinarily leave enough fibrous tissue to permit closure of the openings in the usual manner. Figure 8 illustrates this modified technique.

Collateral circulation. The type of operation required in a given case must to a great extent depend on the adequacy of the collateral circulation. Collateral vascular channels will usually develop to a remarkable degree around an arteriovenous fistula if sufficient time is allowed to elapse. The time factor is all important. In those patients that present themselves to the surgeon quite early it is essential to postpone operation long enough to permit the establishment of good circulation in accessory vessels. However there are two important complications which require early operative intervention despite a doubtful collateral circulation. These are (a) progressive edema and hemorrhage in the tissues around the fistula, producing pressure sufficient to cut off the collateral circulation and threaten the development of gangrene and (b) early cardiac decompensation.

In the presence of a rapidly enlarging hematoma with compression of the collaterals, the usual operation is quadruple ligation with excision. This procedure will stop the bleeding, remove the fistula, evacuate the clot, and relieve the tension. The surgeon can only hope that the collaterals present at the time of operation will be sufficient to prevent ischemia or

gangrene. Restorative procedures or obliterative procedures as a rule cannot be done in such instances.

However it must be remembered that ligation of the main artery in the face of poor collateral circulation is not satisfactory. One case aptly demonstrates the complications that may occur when quadruple ligation and excision is performed before adequate collateral circulation has been established.

CASE 10. G Y was admitted to Charity Hospital suffering from a gunshot wound of the left thigh just below the inguinal ligament. An arteriovenous fistula of the common femoral vessels developed subsequently. Left lumbar sympathectomy was performed 3 weeks after admission, and operation for removal of the fistula was performed 2 weeks later. During operation the femoral artery was found to be involved by considerable scar tissue and was opened accidentally, resulting in a decalson to perform a quadruple ligation. Postoperatively despite sympathectomy the patient's foot was cold and pulseless, and the leg became indurated, swollen, and painful. The patient had to stop smoking and required prolonged treatment with elastic bandages, bed rest, and elevation of the limb for months after operation. Apparently the 5 week waiting period between injury and operation was too short to permit formation of sufficient collateral circulation.

On the other hand, when early cardiac decompensation occurs before adequate collaterals develop the surgeon is faced with an entirely different aspect of the problem. He must then direct his efforts toward eliminating the unprecedented load on the heart.

General Factors

Cardiac status. Impaired cardiac status may manifest itself either as early or late decompensation. Early failure as a result of arteriovenous fistula is relatively uncommon. This is probably due to the fact that larger arteriovenous communications, which immediately overload the heart, often require emergency operative intervention to prevent fatal hemorrhage. Despite the fact that there is not time for collaterals to develop ligation and excision is the usual method used in the treatment of most of these cases. An obliterative endoaneurysmorrhaphy would not be feasible because a false aneurysmal sac requires some time to develop. Furthermore owing to the marked inflammatory reaction in and around the vessels, incident to the trauma, sutures

may not hold at this stage, with the result that arterial repair would be technically difficult and hazardous. The technique using vitalium tubes with a venous graft gives the promise of being a useful operation under such circumstances (Fig 9). Blakemore and Lord have reported considerable success with their elective cases. Unfortunately, recent papers by Rose, Hess and Welch, and DeBakey and Simeone show that poor results were obtained when the nonsuture technique was used for war casualties with arterial injuries. More experience is necessary before the influence of this method can be accurately evaluated.

The development of cardiac symptoms late in the course of this condition is a frequent occurrence and has offered a fruitful field for many investigations. Those patients who show signs of decompensation with cardiac enlargement should be prepared for operation with utmost care. As a routine measure, repeated compression of the fistula preoperatively is advocated to permit adjustment of the heart to the circulatory changes which will occur after operation.

There will be occasional patients who have advanced cardiac disability as a result of a long standing fistula. Price recorded 5 such cases in 1937. Operation was considered impossible in 3 of these patients and only an incomplete procedure could be done in the remaining 2. When myocardial damage is severe a major operation is ill advised. Under such circumstances ligation of the proximal artery and vein or the proximal vein alone may prove beneficial as a preliminary step. These are relatively simple procedures which can be performed under local anesthesia and by reducing the amount of blood pouring back to the heart, may produce temporary relief. If sufficient improvement then takes place the patient will be able to withstand a second operation eliminating the fistula.

Fortunately, the cardiac changes in most instances are moderate and reversible. With careful preparation any one of the three main types of operative procedures can be used depending on the other factors. In the final analysis the cardiac status of a patient will greatly influence the choice of operation because the primary concern of the surgeon is to produce

relief for the decompensated heart. Cure of the fistula then may become a matter of secondary importance.

Generalized arteriosclerosis This causes degenerative changes not only in the vessels involved by the fistula but also in the collateral vessels. Repair of a calcified, arteriosclerotic artery is contraindicated because of postoperative complications such as secondary hemorrhage, thrombosis, and further degeneration of the arterial wall, with subsequent formation of an aneurysm. Quadruple ligation is preferred in such cases despite the risk of poor collateral circulation.

Occupation of the individual Patients who lead a sedentary life and who are rarely called upon to exercise the involved limb strenuously may do well with quadruple ligation. But as Blakemore and others have pointed out strenuous exercise such as that which is experienced by a dancer or by a soldier will require an arterial pathway that is functioning normally.

CONCLUSIONS AND SUMMARY

- 1 Postoperative deficiencies in circulation frequently follow the use of quadruple ligation and excision in the treatment of arteriovenous fistula.

- 2 Recent reports indicate that restoration of the main arterial pathway is the primary objective and should be accomplished whenever possible.

- 3 There are a large number of variable factors which influence the choice of operation for arteriovenous fistula.

- 4 Some factors contraindicate any procedure which interrupts the arterial blood flow. Others contraindicate restoration of the arterial lumen.

- 5 The importance of certain factors both local and general, have been discussed and their relationship to the choice of operation has been considered, with appropriate cases used as examples.

- 6 There is no single operative procedure of choice for all cases of arteriovenous fistula.

- 7 The surgeon must be prepared to use any one of the standard procedures or even an improvised technique in order to overcome individual problems which may be found at operation.

METHODS

Thirty nine unselected cases of various types of surgical infections from the surgical services of three hospitals were used in this study. All of the cases were not followed through to their clinical end results, emphasis being placed on the changes occurring in the bacterial flora of the wound when treated with the urethane sulfanilamide mixture. Some cases were abandoned because of inability to maintain sterility or to abolish the gram negative portion of the bacterial flora; these have been included as failures. The criterion for a response to treatment was the absence or presence of a change in the types and numbers of bacteria in the wound. It was impossible to exercise adequate surgical control in some of the cases.

A thorough history of each case was obtained including the duration of the infection prior surgery and the duration and type of previous chemotherapy. In addition to a careful physical examination a detailed description of the wound was recorded and the patient's age, dietary history, red blood count, hemoglobin and serum protein level were used to classify the patient's physical status. Each infection was classified as acute or chronic. Follow up notes were made, including the type, length of time, and complications of therapy rendered during this study and an assessment of the adequacy of concurrent surgical treatment.

At the time of the initial dressing a nurse was instructed in the proper procedure. Lack of optimal dressing conditions, unco-operative patients, and shifts in nursing personnel occasionally raised doubt as to the faithfulness of dressings, so that an opinion as to adequacy of urethane treatment was recorded for each case (Table I).

Cultures, taken at the time of the initial dressing and every 2 days thereafter were planted on heart infusion-blood-agar plates and in heart infusion blood broth and incubated for 24 to 48 hours. Colony types were identified on the basis of specific diagnostic tests, and an exact bacteriologic diagnosis made in each case. A careful record was kept of the relative numbers of gram negative and gram positive bacteria in each culture, and the time of disappearance of each was noted.

Most of the patients were treated with a mixture of 10 per cent urethane and 1 per cent sulfanilamide. This was prepared by dissolving 10 grams of ethyl carbamate and 1 gram of sulfanilamide in a small quantity of hot water and adding enough water to make 100 cubic centimeters. The solution was then sterilized by passing it through a Mandler filter. A few patients were treated with 10 per cent or 20 per cent urethane without sulfanilamide.

An attempt was made to keep the infected wound in contact with the urethane sulfanilamide solution constantly. This was accomplished by wetting the dressing every 4 hours. All wounds were dressed once a day with careful aseptic technique. Cultures were taken and sterile gauze placed within the infected cavity so as to cover all of the crevices. When applying the chemotherapeutic solutions, the dressings were removed only to the inner layer and the drug applied with a sterile syringe in a sufficient quantity to moisten them well. Sterile gauze was then applied covered with a sterile towel, bandaged and then covered with waxed paper or oiled silk to prevent evaporation. In cases with sinuses or cavities which could not be saucerized or dependently drained a perforated catheter or Dakin's tube was inserted, with sterile gauze loosely packed around it. Injections were made through the catheter every 4 hours and the gauze and catheter changed once daily. Whenever wounds were so located as to be frequently contaminated such as a decubitus ulcer or adjacent to a colostomy the dressings were changed and saturated with urethane sulfanilamide every time contamination with fecal material occurred.

RESULTS

The effect of urethane sulfanilamide mixtures on the gram negative bacteria in infected wounds. Thirty nine patients were studied and their wound cultures revealed a wide variety of gram positive and gram negative organisms. *Staphylococcus aureus*, *Staphylococcus albus*, and *Streptococcus pyogenes* were by far the most common gram positive bacteria present. Twenty-six of the wounds showed mixed infections yielding both gram positive and gram negative micro-organisms. Fifteen of these re-

vealed the presence of *Pseudomonas pyocyanea*, 12 *Proteus vulgaris*, 8 *Escherichia coli* and 3 *Aerobacter aerogenes*. One wound each harbored *Bacillus morgani*, *Klebsiella pneumoniae* and *Eberthella typhi*. In 6 of the wounds *Proteus vulgaris* and *Pseudomonas pyocyanea* were found together. Only 1 case yielded a pure culture of gram negative bacteria. In 20 (Cases 1 to 20) of the 26 mixed infections the gram negative members of the wound flora were eradicated with urethane sulfanilamide mixture. *Proteus vulgaris* and *Pseudomonas pyocyanea* were found to be most susceptible to the action of the drug mixture, these organisms frequently disappearing from the wounds within 48 to 96 hours. Some of the cases (Cases 4, 5, 13, 16, and 19) showed a slower response but were still classified as good results because elimination of the bacteria was accomplished in spite of such obstacles as fecal contamination, inadequate drainage etc. The response observed in these wounds appeared to be significantly better than that following the use of other known topical chemotherapeutic agents. Although the wounds in 8 of the individuals (Cases 4, 5, 7, 8, 9, 10, 11, and 20) had a relatively shallow surface affording good contact with the solution others (Cases 15 and 17) presented situations in which good results were obtained in spite of conditions that were highly unfavorable.

In 7 patients classed as failures, no effect was produced on the gram negative constituents of the wound flora (Cases 21-27). All were in poor general condition, and had either a constant source of wound contamination, inadequate débridement or insufficient drainage. In addition 4 of the patients received inadequate treatment with urethane sulfanilamide solution. The infection was classed as chronic in 18 of the patients whose wounds contained gram negative bacteria and as acute in 9 patients. Six of the 7 failures and 12 of the 20 successfully treated infections were classed as chronic; thus, it would seem that the chronicity of the infection as indicated by the duration of the disease and the presence of thick walled granulations and scar tissue was not important in determining the ability of the drugs to eliminate gram negative bacteria from wounds.

Six patients were treated with a solution containing urethane alone (Cases 6, 7, 12, 15, 16, and 21), of these, 5 showed a good response to treatment, with elimination of the gram negative organisms. These results make it seem doubtful that the antibacterial effect of ethyl carbamate is enhanced by sulfanilamide. In 1 patient (Case 4) who had infected ulcers of both lower extremities, a mixture of 10 per cent urethane and 1 per cent sulfanilamide was applied to the lesions on one leg, and a 10 per cent urethane solution alone to those on the other. There was no demonstrable difference in the results. It appeared, therefore, that the urethane was the component in the mixture most active in killing gram negative bacteria, and that the sulfanilamide exerted little, if any additional effect.

The effect of urethane sulfanilamide mixture on the gram positive bacteria in infected wounds. Gram positive bacteria were present in the wounds of 38 patients. Twenty-six of these showed mixed infections while in 12 only gram positive bacteria were present.

In contrast to the excellent results obtained against gram negative bacteria, urethane sulfanilamide mixture was much less effective against gram positive organisms. Eradication of the gram positive organisms occurred in 12 wounds (Cases 4, 9, 16, 18, 28, 29, 30, 31, 32, 33, 34, and 35), and no effect was demonstrable in 24. In 2 cases (Cases 3, 4) treatment served to eradicate *Streptococcus pyogenes* from the wound but had no effect on *Staphylococcus aureus*, while in several other instances the streptococcus was unaffected by the drug. When good results were obtained, the time required for elimination of the bacteria appeared to be considerably longer than that necessary for gram negative organisms. The possibility exists that a similar effect on the gram positive organisms might have been produced by the meticulous use of saline solution, especially in those cases with shallow wounds. Although these bacteria showed only slight susceptibility to urethane, it may have some value in the treatment of infections by decreasing their pathogenicity. In 1 instance, *Staphylococcus aureus* was noted to change from coagulase positive to coagulase negative and become less actively hemolytic during treatment.

TABLE L—SUMMARY

Case No.	Age Sex	Diagnosis	Duration of infection	Description of wound	Acute or chronic	General status	Previous chemotherapy	Previous surgery	Treatment		
									Type	Time days	Complications
14	34 M	Infected post-operative suppurative wound. Scar to kidney bed	months	Multiple sinus tracts scar to kidney bed. Debrided by lipiodol	Chronic	Good	?	Nephrectomy	10% with 1% salt	30	None
15	37 M	Infected suppurative wound. Scar to kidney bed	1 month	Multiple sinuses to kidney bed from unhealed, discharging suppurative wound	Chronic	Poor	?	Nephrectomy	10% with 1% salt	43	None and vomiting
16	39 F	Osteochondritis of hip, islet seal. Decubitus ulcer	days	Decubitus ulcer over sacrum on distal aspect of buttocks	Chronic	Poor	Dysuria, thrombosis of veins	Hip manipulation	10% with 1% salt	31	None and vomiting
17	40 F	Multiple sinuses of arm and shoulder	1 year	Multiple deep sinus tracts about shoulder girdle	Chronic	Fair	Salicylism, thrombosis of veins, pyrexia	Multiple excision of sinus tracts	10% with 1% salt	44	None
18	41 M	Chronic cystitis, right	14 years	Draining cavity right	Chronic	Good	Salicylism	Rob section	10% with 1% salt	10	None and vomiting
19	41 M	Cancer of colon. Extensive wound infection	weeks	Wound opened widely down to fascia	Acute	Good	Urea solution for weeks	Right colectomy	10% with 1% salt	8	None
20	41 M	Arteriovenous ulcer at base of great toe, right	days	Ulcer with draining sinus at base of toe	Acute	Fair	None	None	10% with 1% salt	4	None
21	64 F	Diabetes mellitus. Sloughing ulcer of foot, postoperative	month	Transverse sloughing undermining postoperative ulcer of dorsum of foot and lower leg	Chronic	Very poor	Salicylism	Amputation of toe	10% with 1% salt	10	Embolism
22	Elderly F	NO I malignancy. Decubitus ulcer		Interphalangeal (old undecubitus) ulcer, with sinuses and sloughing fascia surface on	Chronic	Poor	?	None	10% with 1% salt	5	None
23	38 M	Carcinoma of sigmoid with perforation. Left groin abscess draining spontaneously		Large penetrating wound left groin with sinuses, discharging thick pus. Induration to costal margin. Crepitation to neck	Chronic	Poor		Colonostomy and transverse colectomy both functioning	10% with 1% salt	8	None
24	51 M	Ulcerative colitis with toxic shock. Perirectal abscess	1 month	Perirectal cavity 8x6x6 cm draining perirectal material	Chronic	Poor	None	Debridement. Drainage of rectal abscess	10% with 1% salt	3	None
25	63 F	Hodgkin's disease. Penetration slough in neck	4 months	Foul necrotic sloughing crater in neck extending into neck-stem. Multiple sinuses. No dependent drainage	Chronic	Very poor	Salicylism. Zinc peroxide. Ascorbic acid. Urea crystals	Biopsy of neck lymph node	10% with 1% salt	10	None and vomiting
26	17	Chronic cystitis	10 months	Tube strapped into small sinus in chest	Chronic	Fair	?	Thoracostomy elsewhere	10% with 1% salt	14	Respiratory distress

OF CASES—Continued

Cultures of wounds		Adequate surgical treatment	Adequate urethrae treatment	Clinical result	Bacteriological result	Remarks
Before treatment	After treatment					
<i>Proteus vulgaris</i> <i>Staphylococcus aureus</i> <i>Ps. pyocyanea</i> Diphtheroids	Absent Present Absent Absent	Yes wide open drainage	Yes	Excellent (cure)	Excellent gram negative Poor gram positive	<i>Proteus</i> and <i>Ps. pyocyanea</i> rare after 90 hours' healing (for 16 days). Excellent result demonstrating the use of chemotherapy in conjunction with adequate surgery
<i>K. pneumoniae</i> <i>Staphylococcus aureus</i> <i>Staphylococcus albus</i> Diphtheroids <i>Ps. pyocyanea</i> <i>Proteus vulgaris</i>	Absent Present Absent Present Absent Absent Streptococcus pyogenes	N	Yes	Wound improved clinically	Good gram negative Poor gram positive	Good gram negative result in spite of inadequate drainage <i>Proteus</i> absent in 43 days. <i>Ps. pyocyanea</i> rare colony after 3 days
<i>Ps. pyocyanea</i> Nonhemolytic streptococcus Nonhemolytic staphylococcus aureus Diphtheroids	Absent Absent Absent Absent	Yes	Yes	Excellent. Ulcer sterilized. Grafted—100% take	Excellent gram negative Excellent gram positive	<i>Ps. pyocyanea</i> gone after 3 days. Easily contaminated area
Hemolytic <i>Staphylococcus aureus</i> Each coli	Present Absent	N	No	Poor	Excellent gram negative Poor gram positive	Disappearance of coli 48 hours after treatment
<i>Ps. pyocyanea</i> <i>Staphylococcus albus</i>	Absent Present	N	Yes	Good	Excellent gram negative Excellent gram positive	<i>Ps. pyocyanea</i> gone 48 hours after treatment started. N recurrence
Each coli	Absent	Yes	Yes	Excellent	Excellent gram negative	Wound sterile after 5 days of treatment. Wound edges pulled together with adhesive tape. Complete healing
<i>Ps. pyocyanea</i> Streptococcus pyogenes	Absent Present	No	N	Poor	Excellent gram negative Poor gram positive	Leg amputated on 4th day <i>Ps. pyocyanea</i> gone after 48 hours of treatment
<i>Staphylococcus aureus</i> <i>Proteus vulgaris</i> Diphtheroids	Present Present Present Each coli Streptococcus pyogenes	N	Yes	Patient died	Poor gram negative Poor gram positive	Hopless case. No adequate surgical drainage
<i>Proteus algaris</i> <i>Ps. pyocyanea</i> Each coli <i>Staphylococcus</i> Diphtheroids	Present Present Present Present Present	N	Yes		Poor gram negative Poor gram positive	Abandoned because of lack of surgical control (ulcer needed debridement) and constant fecal contamination. Not fair test
<i>Cl. welchii</i> Each coli <i>Ps. pyocyanea</i>	Present Present Present Streptococcus aureus	No	Yes		Poor gram negative Poor gram positive	Not fair test. Abandoned due to constant fecal contamination
Gram negative bacilli—type undetermined	Present	N	N	Eventually good	Poor gram negative Poor gram positive	Abandoned because of fecal contamination. N fair test
<i>Proteus vulgaris</i> <i>Ps. pyocyanea</i> Streptococcus pyogenes	Present Present Present Staphylococcus	No	N	Poor	Poor gram negative Poor gram positive	Unsuccessful treatment. N dependent drainage. Multiple abscesses
<i>Staphylococcus aureus</i> <i>Ps. pyocyanea</i> Streptococcus pyogenes	Present Present Present	N	N		Poor gram negative Poor gram positive	Adequate treatment impossible because of vomiting. This probably not due to urethane because it only occurred during irrigations

Of the 12 wounds in which elimination of gram positive bacteria was produced the infections in 7 were classified as chronic and in 5 as acute. Nine of the patients were in fair or good general condition, and the clinical status of 3 was poor. Five of the patients in whom good results were obtained had had previous sulfonamide therapy and all except 1 were subsequently treated with a mixture of 10 per cent urethane and 1 per cent sulfanilamide.

Analysis of the 26 failures to eliminate gram positive bacteria from wounds by the use of urethane sulfanilamide solution showed that in 13 there were such obvious reasons as inadequate drainage, constant fecal contamination, etc.

It should be stressed that of the 26 cases of mixed infections in which treatment failed to eradicate the gram positive bacteria, 15 (Cases 1, 2, 3, 5, 6, 7, 8, 10, 11, 12, 13, 14, 15, 17 and 20) showed complete elimination of the gram negative organisms while in none of the 7 gram negative failures were the gram positive organisms in the same wound eradicated. These cases show the highly selective action of urethane dependent on the staining reaction of bacteria.

Complications. Careful observation failed to reveal a hypnotic effect in any of the 39 patients treated by the topical application of urethane. One patient was given 10 grams of urethane orally in 24 hours without untoward reaction. Nine of the topically treated individuals suffered from nausea and vomiting, 2 from nausea alone and 1 from retching. These symptoms were at times severe enough to cause moderate discomfort and were sufficiently alarming to warrant discontinuation of the drug in 1 instance (Case 26). In this patient psychogenic factors were thought to play a large part. The nausea usually began after 3 or 4 days of treatment, reached a peak on the fifth or sixth day and then decreased, to continue moderately thereafter. The 12 patients who showed these symptoms were treated for an average of 19 days, the shortest being 9 days and the longest 43 days. Seven of those who had gastrointestinal symptoms had previously received some type of sulfonamide. In the remaining 5 patients no information concerning the previous use of these

drugs was available. That the nausea and vomiting were not due to sulfonamide sensitivity was borne out by the fact that they occurred in 3 individuals who were treated with urethane solution alone. The wounds in 10 of the 12 patients who had gastrointestinal disturbances were relatively large, and it was our impression that the symptoms occurred more frequently when large surface areas of normal surrounding skin were kept constantly moist with urethane solution. This suggested that the drug was absorbed through normal skin, and other observations tended to bear out this theory. One patient, not included in this study who had severe pyoderma over the entire thorax and trunk and was treated with a large amount of urethane suffered very severe nausea and vomiting. During the latter part of the investigation, therefore, the normal skin was covered with vaseline gauze up to the wound edge in order to prevent absorption. With this type of management no other instances of nausea or vomiting were seen.

SUMMARY AND DISCUSSION

Meleney (16) has called attention to the difficulty of appraising the value of drugs used for the treatment of surgical infections and has enumerated many factors which must be taken into consideration in evaluating their efficiency. In certain acute surgical infections, a series of unselected alternate patients with relatively few variables can be treated under standard conditions, and the value of a chemotherapeutic agent assessed quite correctly. In the cases reported here in which most of the wounds were chronic, occurred in patients with a wide variety of underlying conditions, and included some which had been previously treated by various methods, it is difficult to assess the value of an antibacterial agent because of the lack of adequate controls. It is necessary, therefore, to use the patient's previous response to other types of therapy as a control and to stress the importance of changes in the bacterial flora. In order to conclude that ethyl carbamate is of value, the results obtained must be significantly better than those expected after other types of treatment.

As can be seen from the data presented, urethane has a selective action against gram

negative organisms. These results are in accord with those previously described in *in vitro* studies. The reason for this selectivity is not known but it would appear to be of great value in the treatment of wounds with mixed infections since, with the exception of streptomycin, there are few agents which are highly active against gram negative organisms.

Most of the patients in this study were treated with a combination of sulfanilamide and urethane. Several cases given carbamate alone appeared to show as good a response as those receiving a combination of the drugs, and it is our impression that the addition of sulfanilamide may not be necessary. *In vitro* studies of ethyl carbamate separately and in combination with sulfonamide yielded the same results, although a slight synergistic effect could be demonstrated when the two drugs were combined. It has been shown by Weinstein that penicillin plus urethane will inhibit greatly the growth of mixtures of gram positive and gram negative bacteria in the test tube. These data suggest the possibility of using a mixture of urethane and penicillin in the treatment of wounds. With such a combination the gram positive organisms should be killed by the penicillin and the gram negative organisms by the carbamate. An agent potentially bactericidal for the gram negative group should prevent or limit their production of substances such as penicillinase (1) which inhibit the action of penicillin and should thus render the latter more efficacious.

Urethane showed no deleterious effect on tissue healing since large wounds were found to heal promptly after being sterilized. Skin grafts took successfully when postoperative dressings were kept continuously saturated with urethane (Cases 4, 9, 11 and 8). Epithelialization was observed to progress at a normal rate in the constant presence of 10 per cent urethane solution.

The complications seen in patients receiving urethane have already been described. Nettleship, Henshaw and Meyer have called attention to the carcinogenic effect of ethyl carbamate in mice. These investigators increased the incidence of lung tumors in C₃H female mice¹

from less than 5 per cent to more than 75 per cent by minimal anesthetizing intraperitoneal injections of urethane, by a dose of 1 milliliter of a 10 per cent aqueous solution per 100 grams of body weight. Haddow and Sexton (5) on the other hand have shown that urethane has a growth inhibiting effect on animal tumors, and Paterson, Haddow, Thomas, and Watkinson (19) have recently reported beneficial effects from the use of urethane in myeloid and lymphoid leucemia, carcinoma of the breast, lymphosarcoma, Hodgkin's disease and other malignant lesions.

In some of the cases reported in the present study, the quantity of urethane used probably exceeded the level used by Nettleship and co-workers, but it was employed as a topical agent and was not administered parenterally. Although some was undoubtedly absorbed through the skin or wound it does not appear likely that the amount was as great per unit of body weight as that given intraperitoneally to mice by Nettleship and his co-workers. There would appear to be little to fear regarding the carcinogenic effect of urethane in man. The fact that the incidence of tumors in a known tumor susceptible strain of mice is increased by the administration of some substance does not mean that such a result would follow the use of the same material in man. For example, the administration of estrogenic substances is known to enhance the occurrence of breast tumors in mice, yet these agents have been used very extensively in women.

Although urethane has been shown to be very effective against gram negative organisms and to allow normal wound healing it must be remembered that the use of this or any other drug does not replace the application of sound surgical principles. Experience in World War II (2, 12, 28) has demonstrated that the presence or absence of bacteria is not important in choosing the proper time for suture of soft tissue wounds, failure having followed the closure of clinically dirty wounds which were sterile and success having resulted after suture of wounds massively contaminated with staphylococci and streptococci. It is not reasonable to expect the eradication of bacteria to result from the topical application of a chemotherapeutic agent to wounds in which the

*The "plunge" of gelatin is an expression of its gel strength and is determined by the weight required to make a 15 mm penetrator give depth at 4°C.

plunge gelatin i.e. slightly degraded or markedly degraded material have not been well established. This study was undertaken therefore from the viewpoint of comparing the efficacy of different concentrations of gelatin and of gelatins of varying degrees of hydrolysis.

In Table I are listed the variety of gelatins tested and some of the pertinent information obtained.

We attempted to use animals with a medium factor of probability of survival (1 700-3,000) and with medium carbon dioxide (20-30 volumes per cent) value except when 2 per cent gelatin and saline were employed. With the latter two materials we purposely chose animals with a high factor of probability of survival and a high carbon dioxide value because it became clear very early that these substances were relatively ineffective.

Methods. The experimental procedure and methods used were those described previously (1) with one exception after the hemorrhage, the blood was quickly centrifuged the supernatant plasma removed and at the reinfusion, a volume of test material equal to the removed plasma was injected followed by the packed red blood cells. There could not be complete substitution of the test material for the plasma, for about 6 per cent of the latter was retained around the packed red blood cells and reinfused with them. This was constant however for the varying substances tested. Blood pressures were recorded continually from a

carotid artery. One femoral artery was used for bleeding and for withdrawal of blood samples for analysis. All surgical procedures were performed on dogs under local anesthesia (procaine).

RESULTS

Antishock properties and survival. The efficacy of the gelatin was based on the period of survival of the animal. In the tables, D E. signifies death occurring during the experiment. D N indicates longer survival but death during the night following the experiment and I S means indefinite survival, in which group we placed all animals alive 48 hours after the experiment. Rarely did an animal fail to survive indefinitely if it was still alive 24 hours after the experiment. Table II presents a summary of all experiments. The data previously obtained (1) when whole blood was reinfused are included for comparison at the bottom of the table. The results presented in this table lead to several clear-cut conclusions.

1. Confirming the previously expressed results, most animals with a carbon dioxide value less than 20 volumes per cent and a factor of probability of survival under 1 700 will not survive regardless of the reinfusing fluid, even when whole blood presumably the best, is used.

2. Animals with a carbon dioxide value above 30 volumes per cent and a factor of probability of survival above 3,000 have a good prospect of survival if the reinfusing agent has definite restorative properties.

3. On the basis of our criteria, saline has the least value in saving animals.

4. Two per cent gelatin is only little better than saline.

5. Four per cent gelatin has definite value, is strikingly better than saline but is somewhat inferior to gelatin of higher concentrations.

6. Gelatin of 6 to 8 per cent concentration is a very effective agent. The relative merits of the different concentrations and plunges are not so clearcut. Statistical analysis of the results, by the chi square test, discloses that there is no overall difference between blood and gelatin and, in general, all the higher concentration gelatins are equivalent. Statistical

F P S.—Factor of probability of survival.

*D. E. signifies death occurring during the experiment; D N during the night; and I. S. indicates survival.

low plasma protein content delays recovery particularly if there is a complicating infection. In such cases, the plasma proteins should be restored as rapidly as possible to normal levels by plasma or whole blood administration and proper nutrition.

Gelatin is an effective agent in combating shock due to plasma loss and should be a valuable addition in our therapy if the gelatin is used with due regard to its properties and limitations.

SUMMARY

The efficacy of gelatin solutions in the treatment of hemorrhagic shock was tested.

Various brands of gelatin gelatins with different degrees of hydrolysis and various concentrations of gelatin solutions were tried in our experiments.

Our method of repeated graded hemorrhages and reinfusion of the blood 30 minutes after each hemorrhage was used as control. In the assays of the gelatin solutions the plasma of the withdrawn blood was replaced by a gelatin solution.

The factor of probability of survival and the critical carbon dioxide value were used to predict the chance of survival of the individual animal. Prolongation of the periods of survival served as criterion of the efficacy of the gelatin solutions.

Gelatin solutions of 2 per cent concentration do not prolong life of the shocked animal appreciably and therein resemble physiologic saline solution.

The best results were obtained with gelatin solutions of 6 and 8 per cent concentration. The effects of these solutions with the packed cells were as good statistically as reinfusion of whole blood.

The degree of hydrolysis of the gelatins in the range tested by us did not seem to be an important factor in the efficacy of the gelatin as plasma substitute.

Gelatin solutions must be pyrogen free and should be liquid at room temperature.

In the dog, gelatin is excreted rapidly in the urine with the exception of 6 per cent bone gelatin which left the circulation at a slower rate than the skin gelatins.

Gelatin solutions dilute the blood and lower hemoglobin and protein values. In some cases

plasma and red cells must be given later in the treatment.

Following our experience in the dog we do not hesitate to recommend gelatin solution for use in patients. Gelatin cannot replace whole blood, nor is it a substitute for plasma, but has value as an inexpensive easily available agent to combat shock due to plasma loss. Our experience with the use of gelatin solution in the patient has been favorable.

evidence of previous breast disease recorded in the case histories, although it seemed inconceivable that caked breasts, should not have occurred in some cases. There was no history of trauma in the entire series.

Duration The duration of this condition before the patients sought treatment was difficult to determine with accuracy. A few admitted having a lump in the breast for months but the great majority insisted that it had been present for only 2 weeks or less in 14 for 3 to 7 days, in 7 for 8 to 16 days, in 6 for 3 to 4 weeks, in 4 for 3 months, and in 1 for 3 years. The older women were more or less reticent regarding their breast tumors this was especially true of negro women who had a great fear of operations. However the patients were questioned very carefully on this particular point and their answers were at variance with the operative findings. It is difficult to picture a mass the size of a tennis ball, with a dense fibrous wall an inch or more thick surrounding a central pus pocket containing a dram of pus, developing in 2 weeks or less.

Approximately one third of the patients noticed that the tumor mass had enlarged rapidly in the last few days before admission to the hospital. We believe these lesions to be long standing and will elaborate this phase further under the pathological discussion.

Symptoms The symptoms were varied: lump in breast in 30 swelling of breast in 3 pain at onset in 11 late pain in 5 no pain in 6 heavy sensation in 3 squeezing sensation in 1 burning in 1 discomfort in 1 tenderness in 6 pain in nipple in 1 itching of nipple in 1 discharge from nipple in 2 tumor enlarging rapidly in 9 fever (early) in 5 swelling in axilla in 1. Of these the most important were the lump in the breast, the various interpretations of pain or discomfort, the early fever and the recent rapid enlargement of the mass.

Physical findings The tumor was described as hard in 19 indurated in 3 lobulated in 1 rough in outline in 1 firm in 9 nonfluctuant in 1 circumscribed in 3 nodular in 1 irregular in 2 regular in 3 stony in 1 adherent to skin in 11 not adherent to skin in 7 not adherent to underlying tissues in 5 movable in 4. The overlying skin was orange peel in 4 red in

1 and increased temperature was noted in 2. Five patients had retraction of the nipple and in 1 instance ulceration was present. The breast was tender in 8 but in 10 tenderness was recorded as being absent. The axillary glands were palpable in 9, not palpable in 5 hard in 3 and adherent to the skin in 1.

We are all familiar with the cardinal signs of moderately advanced breast cancer the hard lump fixed in the breast tissue, flattening or dimpling of the overlying skin when squeezed gently adherence of the tumor to the skin and underlying tissues, retraction of the nipple poor transillumination of the breast, the orange peel skin and enlarged, hard axillary lymph nodes. Circumscribed chronic suppurative mastitis may present any or all of these characteristics.

In this series of cases, the leucocyte count and the polymorphonuclear percentage were within normal limits in all but a few cases, and in no instance was an increase in eosinophils noted. Temperature in the 100 degrees F group was observed in 25 per cent of the cases and there was only 1 instance of 101 degrees F or more.

Diagnosis The differential diagnosis of breast lesions is of the greatest importance. To overlook a malignancy is a serious mistake. With circumscribed chronic suppurative mastitis the problem of diagnosis is reversed but no less important. The performance of a radical mastectomy where less extensive surgical treatment will suffice is also a grave error. Patients with circumscribed chronic suppurative mastitis are often seen in that stage of the disease which most closely simulates cancer and hence differentiation of these two diseases is difficult and requires careful evaluation of all available information.

The duration of the symptoms is important in spite of the fact that the operative findings point to a lesion of long standing. The history of 2 weeks or less duration with recent rapid enlargement of the tumor mass should be of maximum importance in the differentiation as this is unlike the progress of a malignant tumor.

Pain at the onset always points toward an inflammatory lesion although this may vary with the individual and in some instances be entirely absent. It should also be remembered

that pain may be present in malignant tumors that have attained this stage of development.

The symptom of early fever is less reliable and by the time the patient enters the hospital will have subsided.

Tenderness on palpation is of about the same value as pain. It will vary with the individual and may be absent in half the cases. It, too, can be present in a malignant tumor that has reached these proportions.

Increased surface temperature or redness over the lesion is rare but, if present, points very strongly toward inflammation.

After careful evaluation of the symptoms and physical findings there will remain about one-third of the cases in which surgical exploration is necessary for diagnosis.

Preoperative biopsy for breast tumors including aspirations, punch biopsies, and those procedures which remove only small bits of tissue we consider entirely inadequate. Positive findings in borderline cases may be inconclusive and negative reports simply show there is no evidence of malignancy in the tissue submitted. In this institution frozen sections are rarely done except under special circumstances. After several unfortunate experiences the procedure was discarded as unreliable for breast tumors and a rapid 24 or 48 hour paraffin method substituted. We have made it a rule to send all of the tumor to the pathologist for biopsy whenever possible even should it include the entire breast. To do less is unfair to the patient and the pathologist.

The preoperative diagnoses in this series were chronic mastitis 5, chronic cystic mastitis 1, abscess 7, tumor type undetermined 8, carcinoma, 7, carcinoma with axillary metastases 4.

PATHOLOGY

Although minor variations may be present, both the gross and microscopic pathologic features of this lesion are distinctive. The tumor varies considerably in size. When palpated through the skin such terms as size of a large walnut, hen's egg, plum, lime and orange were employed. In actual measurement the tumors varied from the smallest, 2.0 centimeters in diameter to the largest 11.0 by 9.0 by 5.0 centimeters. The shape is ovoid rather than round. The

tumors cannot be peeled away from the surrounding breast parenchyma without great difficulty as no actual cleavage planes are present. Sharp dissection is necessary either at the operating room table or at the pathological examining board.

The essential characteristics of the lesion are best seen if the tumor is hemisected. There will be found a central abscess filled with gray yellowish gray, or greenish pus. This purulent center is always small in relation to the mass. Often it measures only 0.5 centimeter in diameter even in the largest tumors. Occasionally the abscess measures 5.0 centimeters in its greatest dimension but this is distinctly unusual. An average abscess measures 1.0 to 1.5 centimeters in diameter. This pus is rather thick and does not flow easily. When the pus is removed a shaggy gray or grayish green lining is observed. In a few specimens two or three small abscesses of a similar nature are found instead of one central abscess. Occasionally the larger abscess communicates by narrow channels with smaller satellite abscesses.

The bulk of the tumor is composed of dense, firm white tissue surrounding the abscess. This can be cut with moderate resistance and a slightly gritty sensation. Frequently the tissue is so hard as to be grossly indistinguishable from carcinoma. The wall of the abscess measures from 1.0 to 5.0 centimeters in thickness. For this reason if the tumor is cut tangentially or if the section misses the abscess, only firm white tissue strongly resembling carcinoma is found. The tumor blends gradually into the adjacent parenchyma which is rubbery and rolls under the cutting knife. One side of the tumor may be close enough to the skin to be adherent to it and it is in these cases that wrinkling of the skin is prominent.

The axillary lymph nodes are enlarged, some measuring as much as 3.0 centimeters in their greatest dimension. They are discrete and firm and on sectioning appear uniformly gray or somewhat mottled but no hard white areas indicative of metastases are seen.

Microscopically the abscess is filled with polymorphonuclear leucocytes, generally in a fair state of preservation. Occasionally many fat-filled macrophages and a few lymphocytes

A COMPARISON OF SUTURE AND NONSUTURE METHODS FOR THE ANASTOMOSIS OF VEINS

THOMAS N P JOHNS M.D., Baltimore, Maryland

THE introduction of an improved method of blood vessel anastomosis by Blakemore and Lord (3) in 1942 put a new and practical tool into the hands of the vascular surgeon. This method made use of the principle that two vessel ends can be successfully joined over a tube of inert metal (vitallium) provided the inside of the tube be lined with intima, thus it reaffirmed the long known axiom (8) that intimal integrity and continuity are the essence of permanent blood vessel patency. The advantages of the new nonsuture method were asserted to be chiefly (1) the technical ease and speed with which the anastomosis could be performed, especially under battle conditions where the immediate re-establishing of blood supply was essential to the life of a part, and (2) the fact that a gap could be bridged.

This nonsuture anastomosis was in fact first devised as a means of bridging arterial defects (3, 4) a segment of prepared vein was used to line the gap between the divided ends of an artery. However the method has since been applied by Blakemore (2) and others to vascular problems in which there is no defect to be bridged i.e. to cases amenable to the old direct suture method of anastomosis (5, 6). Notable among such cases has been the portal caval anastomosis for the relief of portal hypertension (2). Such a procedure may consist in (1) an end-to-end anastomosis between the proximal ends of the divided splenic and left renal veins following removal of the left kidney and spleen or it may mean (2) the anastomosis of the divided distal end of the portal vein to the side of the inferior vena cava.

The question therefore arises whether the newer nonsuture method is preferable to anastomosis by suture. In cases in which either procedure is feasible, is the nonsuture anas-

tomosis better than the old direct suture method? And what are the advantages and disadvantages of each procedure? The results of the few reported cases in which the vitallium tube has been used are promising. The advantages of technical ease claimed for this procedure are undisputed. But current developments and the recently observed potentialities of blood vessel surgery demand a more thorough comparison of the two methods and their merits.

The primary consideration in all blood vessel surgery—far from being any refinement of technique *per se*—is, of course, the functional efficiency of the vessel as a conductor of blood. Compared to this all other factors are secondary and contributory in their importance. Unless a given procedure produces results at least comparable to those of other methods, no technical advantage justifies its use. A valid analysis and comparison of two such different methods would have to be on a functional basis. Anastomoses would have to be performed by each method under similar conditions and on the same vessels in a number of experimental animals, and delayed observations made of the functional patency of all these anastomoses. The purpose of this report is to present a summary of such observations.

PROCEDURE AND TECHNIQUE

The renal splenic vein anastomosis was considered angularly suited to this comparative study since it would eliminate certain external and mechanical factors which might introduce an inconstant error. From a physiological standpoint, the pressure gradient between the portal and caval systems in normal dogs is small, 30 to 50 millimeters of water (1). This means that the sheer mechanical pressure effect of flowing blood in keeping the anastomosis open is reduced to a desirable minimum.

In these experiments dogs weighing between 15 and 25 kilograms were used. They were

From the Department of Surgery of the Johns Hopkins University and the Johns Hopkins Hospital.

TABLE I.—RESULTS END-TO-SIDE SUTURE ANASTOMOSIS

Dog	Day after operation	Function	Microscopic
	(Dead)	Patent	N section.
16	(Dead)	Thrombosed	No section.
3	75 (Sacrificed)	Patent	No thrombus
4	74 (Sacrificed)	Patent	Slight intimal thickening.
5	(Sacrificed)	Patent	3 mm. thrombus along splenic vein.
3	3 (Sacrificed)	Patent	Slight intimal thickening
16	27 (Sacrificed)	Patent	No thrombus.
8	2 (Sacrificed)	Patent	N thrombus.

20	70 (Sacrificed)	Patent	No thrombus

anesthetized with intratracheal ether. In order to avoid errors of technical variation the types of anastomoses were performed alternately and by the same operating team. At intervals of 12 to 75 days following operation autopsies were made on the dogs. The anastomoses were examined grossly for functional patency and thrombosis, and microscopically for intimal changes and the presence and type of thrombi.

Three series of operations were performed. No anticoagulant was used in any of these experiments.

In the first series the proximal end of the divided splenic vein was anastomosed into the side of the intact left renal vein. The anastomosis was done by the classic method of Carrel and Guthrie (5, 6). There were 10 dogs in this series.

In the second series in which 11 dogs were used the spleen and left kidney were removed and a suture anastomosis was performed between the proximal ends of the splenic and left renal veins. With fine silk and straight needles, three stay sutures were placed to insure proper alignment and a continuous running suture was employed with care to approximate intimal surfaces by everting the edges of the veins.

In the third series, after splenectomy and left nephrectomy the ends of the renal and splenic veins were anastomosed over a vitallium tube by the method described in detail by Blakemore (2, 3, 4). The end of the splenic

vein was brought through the tube and everted over its edge, being secured here by silk ligatures placed behind tying ridges on the outside of the tube. The end of the renal vein was then very carefully brought over the outside of the vein lined tube and secured tightly by two silk ligatures, one behind the tying ridge and one just behind the edge of the tube. Twelve anastomoses were done in this series.

RESULTS

There were no operative or early postoperative deaths among the 33 dogs in the three groups of experiments.

In the first series (Table I) of the 10 end-to-side suture anastomoses, one was completely thrombosed after 16 days. Nine were functionally patent after periods of 12 to 74 days of these, 1 showed a microscopic thrombus extending 5 millimeters along the lumen of the splenic vein, 2 showed negligible intimal thickening at the suture site and 5 were absolutely clear microscopically. No sections were made of the remaining 2. The silk suture material was unabsorbed even after 75 days, but the foreign body reaction was not remarkable. The over all patency was 90 per cent.

Of the 11 end-to-end suture anastomoses, (Table II) 3 were completely obstructed by organized thrombi at 46, 55 and 51 days. Eight were functionally open after 13 to 55 days. 4 of these showed microscopic thrombosis which was functionally negligible there was slight intimal thickening in 2 in the remaining 3 the anastomoses were clear. There was 72.7 per cent patency.

Of the 12 anastomoses performed by the non-suture technique only 2 were patent (Table III). Both of these were in animals sacrificed 14 days after operation. The remaining 10 were completely thrombosed after periods varying from 14 to 52 days. In all cases the thrombi were found to obliterate the vessel lumina throughout the entire length of the vitallium cannulas. There was microscopic evidence that the thrombotic process began in the renal end of the cannula and progressed down the splenic vein since in most cases the fresher part of the thrombus was at the splenic end of the anastomosis. There was some recanalization but this was of no functional

TABLE II.—RESULTS END-TO-END SUTURE ANASTOMOSIS

Dog No.	Days after operation	Function	Microscopic
6	27 (Sacrificed)	Patent	No thrombus has eroded suture at one point.

			Old thrombus filling entire lumen

importance. In this group there was 17 2 per cent patency

COMMENT

The results of these experiments indicate that in vein anastomosis, through which the blood flow is relatively small e.g. splenic renal shunt, the suture method judged by functional patency is superior to the nonsuture method.

The fact that the nonsuture technique has met with greater success in arterial anastomosis than in this series may be attributed partly to the mechanical effect of the pressure of the arterial blood flow in maintaining patency. This factor should also contribute to comparably better results in direct suture arterial anastomoses.

In this connection work by Murray and Janes, at Toronto has shown that arterial anastomosis over metal bands leads to necrosis of the vessel wall with resulting hemorrhage in many cases. Suture anastomoses did not show this in any of their cases.

In addition to its demonstrated functional inferiority in this particular vein anastomosis, the nonsuture method has two important drawbacks pertinent to arterial as well as venal surgery (1) It leaves a large foreign body in the tissues. (2) The metal tube is not expansile

and hence the anastomosis cannot increase size subsequently.

Regardless of the technique of anastomosis used in this portal caval shunt, the end-to-end anastomosis would seem preferable to the end-to-end anastomosis because (1) it preserves the left kidney and (2) it provides a greater flow of blood—from the left kidney—past the anastomosis a factor which should be helpful in preventing thrombosis.

There is no implication here that the direct suture rivals the nonsuture method for bridging defects of arteries and veins. It is also apparent that the suturing of vessel ends is inferior to the vitallium tube when there is any appreciable tension on the anastomosis. In these important respects, the method of Blakemore is a major contribution. We conclude however that for cases in which a suture anastomosis can be performed without undue tension this procedure is preferable to the nonsuture method and remains the technique of choice.

SUMMARY

1 Experiments were performed on dogs to determine the relative merits of two accepted methods of blood vessel anastomosis the di

rect suture method of Carrel and Guthrie and the nonsuture method of Blakemore.

2 Anastomoses were performed (a) by suture between the proximal end of the divided splenic vein and the side of the renal vein (b) by suture between the proximal end of the splenic vein and the proximal end of the renal vein and (c) by the nonsuture vitallium tube method, between the proximal end of the splenic vein and the proximal end of the renal vein

3 Delayed observations showed a higher percentage of functioning patent anastomoses in the suture groups (90% and 72 7%) than in the nonsuture group (17 2%)

4. It is concluded that in blood vessel anastomoses where there is no tension on the suture line and no defect to be bridged the

suture method of anastomosis is superior to the nonsuture method. In other cases the nonsuture technique of Blakemore is probably better

ORIGIN AND DEVELOPMENT OF THE ERECT POSTURE

CLARENCE A SPLITHOFF M D Oakland California

MAN with childlike innocence has always considered his erect posture a God given blessing Milton in *Paradise Lost* said that in the Garden of Eden there were

Of living creatures new to sight and strange.
But all kind

Two of far nobler shape, erect and tall,
Godlike erect, with native honor clad,
In naked majesty seemed lords of all,
And worthy seemed."

Man's erect spine has been one of his greatest assets yet to all intents and purposes also one of his greatest liabilities. Because of it the forelimbs have been divorced of their former function of locomotion and developed into organs of prehension. This fact has enabled man to become master of his domain. Despite this apparent superiority man's low back is a weak spot, a so called 'Achilles heel'. Since man is the only living creature endowed with unconditional erect posture it may be well to examine this inheritance to shed new light on the problem created by his ability to walk erect.

The pelvis and hind limbs appeared first as keels or ridges supported by basal rods operated by extensions of the segmental muscles of the body wall. Later they became paddle like and finally were bent downward and strengthened to support the body on land, and to cooperate with the pectoral limbs in pushing the body forward (2).

The pelvis arose in close association with other bodily functions those of digestion and excretion and also of reproduction in the discharge of eggs or living young in the female and of sperm in the male (Fig 1). The pelvis thus arose around the cloaca and served as a base or platform for certain groups of muscles those running forward along the lower surface of the abdomen those running backward along the under and outer sides of the tail and a cone shaped mass of muscles based on the pelvis

and converging outward and downward to form the thigh muscles.

The ilium at first grew upward between the muscles of the back in front and the tail muscles behind. In so doing it passed to the sides of the ribs being at first entirely free, later becoming tied to them by connective tissue and ligaments and still later by bony connection.

Although we are not sure of the date when human posture evolved we are quite certain that it became adjusted through a series of changes from arboreal to terrestrial existence.

(3) These changes can be readily observed by a comparative study not only of living primates but of fossil material beginning with the Devonian lobe fin Eusthenopteron (Fig 2 a) a prehistoric fish. In this animal which existed about 350 million years ago formed the earliest evidence of a pelvic girdle consisting of a pair of bony rods on either side of the cloaca. It supported the pelvic fins which were moved by simple opposing groups made up of folds of the outer myomere.

Further development occurred after the fin fish came out on land. The iliac blades upward becoming attached to the sacral region and thus to the vertebral column. Thus found in the earliest amphibians about 300 million years ago in the carboniferous age of which Eogyrinus (Fig 2 b) is an example.

In the ancient amphibians such as Eryops megacephalus (Fig 2 c) the pelvis was shaped like the body was slung by muscular straps attached to the pelvis much as the cables of a suspension bridge. The iliac blades were attached to the spine by ligamentous attachment to the sacral ribs. The limbs were widely spread apart and walking was cumbersome. The Cynognathus (Fig 3 d) from the upper Triassic of South Africa, about 175 million years ago represented an intermediate stage of the reptile and the mammal. The limbs were adapted for running and there were many features of the skull backbone and limbs that approached those of mammals. The iliac blade

was wider and was more firmly attached on a broader base to the spine

As a representative of the next stage in development, the opossum (Fig. 3 e) may be studied (5). It retains, in the main the leading characteristics of the skeleton of the older fossil animals. The iliac blade is elongated and inclined forward. The limbs contain five-toed grasping hands and feet, by which it made its way about in the trees. In these early mammals when the knees were drawn forward the ilium also grew forward almost parallel with the backbone to which it was now attached by means of the sacral vertebrae and their ligaments, the sacral ribs having become short and wide and fusing with the transverse processes of the sacral vertebrae.

The order of primates to which man belongs made its appearance early in Eocene times, about 60 million years ago in the form of an arboreal monkey-like animal *Notharctus* (Fig. 4). Adaptation to tree climbing was quite well

advanced which is obvious from certain features of the skeleton such as the grasping type of construction of the hind feet. It is highly significant that all of the known foot and limb bones of fossil lemurs, monkeys and apes are unquestionably of arboreal type. Hence one must infer that the origin of the order of primates as a whole was arboreal. This fact is of importance in the question of man's origin and brings us to a consideration of the relationship between man and ape.

It is not certain when the separation of man from the primitive anthropoid stock occurred however it must have been during the Miocene epoch somewhat over 20 million years ago. No fossil showing the transformation has been found and only by deductive and inductive inference have we been able to reach any conclusion. There is, however some difference of opinion regarding man's origin. Professor Osborn states, "I personally had abandoned the anthropoid ape theory and I advanced the

opinion that man has a long line of dawn ancestors and that the other theory rests upon a large amount of evidence which proves the kinship of anthropoid apes to man but does not prove the ancestry of man through an anthropoid ape type. He further quotes Sir Arthur Keith who is of the opposite opinion stating that all the evidence now at our disposal supports the conclusion that man has arisen from an anthropoid ape not higher in the zoologic scale than a chimpanzee (?)

Man and ape possess certain characteristics in common, such as a high mentality, a prehensile hand, an erect or semierect posture, etc. However, there are certain skeletal and developmental differences which I propose to examine to obtain a clearer understanding of the evolution of the erect posture.

The gibbon, an East Asiatic tree living descendant of the first family of tailless or man-like apes is the only ape normally walking on its hind legs when on the ground. The skel-

was wider and was more firmly attached on a broader base to the spine.

As a representative of the next stage in development, the opossum (Fig. 3 c) may be studied (5). It retains in the main the leading characteristics of the skeleton of the older fossil animals. The iliac blade is elongated and inclined forward. The limbs contain five toed grasping hands and feet by which it made its way about in the trees. In these early mammals when the knees were drawn forward the ilium also grew forward almost parallel with the backbone to which it was now attached by means of the sacral vertebrae and their ligaments the sacral ribs having become short and wide and fusing with the transverse processes of the sacral vertebrae.

The order of primates to which man belongs made its appearance early in Eocene times, about 60 million years ago in the form of an arboreal monkey like animal *Notharctus* (Fig. 4). Adaptation to tree climbing was quite well

advanced which is obvious from certain features of the skeleton such as the grasping type of construction of the hind feet. It is highly significant that all of the known foot and limb bones of fossil lemurs, monkeys, and apes are unquestionably of arboreal type. Hence one must infer that the origin of the order of primates as a whole was arboreal. This fact is of importance in the question of man's origin and brings us to a consideration of the relationship between man and ape.

It is not certain when the separation of man from the primitive anthropoid stock occurred however it must have been during the Miocene epoch somewhat over 20 million years ago. No fossil showing the transformation has been found and only by deductive and inductive inference have we been able to reach any conclusion. There is, however some difference of opinion regarding man's origin. Professor Osborn states, "I personally had abandoned the anthropoid ape theory and I advanced the

opinion that man has a long line of dawn ancestors and that the other theory rests upon a large amount of evidence which proves the kinship of anthropoid apes to man but does not prove the ancestry of man through an anthropoid ape type. He further quotes Sir Arthur Keith who is of the opposite opinion stating that all the evidence now at our disposal supports the conclusion that man has arisen from an anthropoid ape not higher in the zoologic scale than a chimpanzee (?)

Man and ape possess certain characteristics in common such as a high mentality, a prehensile hand, an erect or semierect posture, etc. However, there are certain skeletal and developmental differences which I propose to examine to obtain a clearer understanding of the evolution of the erect posture. The gibbon, an East Asiatic tree living descendant of the first family of tailless or like apes is the only ape normally walking only on its hind legs when on the ground. The

eton begins to be almost human (Fig. 3 g) however the arms are excessively long because of its brachiating habits. Its pelvis begins to show incipient widening of the iliac blade as compared with the lemur (Fig. 3 f) one of a group of monkeys (Lemuroidea) which exist entirely in trees. In the lemur the ilium is narrow and is adapted for running and leaping. At first in the mammals the upper part of the ilium was triangular in cross section, its three surfaces being occupied respectively by the muscles of the upper side of the backbone, by the iliacus muscles in front and by the gluteal muscles on the outer side. When the primates began to sit upright, resting themselves on their folded legs and on the lower ends of the pelvis the iliac muscles served to check them from falling forward. Thus with increased size of these two muscles the blade of the ilium began to grow outward in a transverse plane the chief successive steps in this broadening process being recorded in the lemurs, monkeys, apes, and man (Fig. 3 f, g, h, and i).

Since the gibbon has been endowed by nature with the ability to walk upright it may be well to pause at this point and learn how this came about. The body of the primitive quadruped is slung between two suspension towers, which are the pelvic and pectoral girdles. The gibbon has succeeded in turning this suspension bridge up at right angles to its original horizontal position and in balancing it on the rear tower represented by the pelvic girdle. Thus nature has worked out in this animal the basic invention for upright or bipedal progression. This step can be seen in the viscera which approach the human type in a number of ways, and in the details of construction of its pelvis.

The gibbon learned to run on its hind legs by first learning the habit of sitting upright, and secondly by the habit of brachiating or climbing with the arms raised above the head and the body suspended beneath the branches. The habit of sitting upright conditioned the first steps in the remodeling of the pelvis, especially the flattening of the ilium in the transverse plane. The habit of brachiating conditioned the extension to and upon the ilium of certain muscles of the loins and abdomen, thereby being better able to support the vis-

cera, pelvis, and hind limbs when the body was suspended by the arms. In addition to climbing the gibbon makes enormous leaps from one branch to another and in so doing has developed great extension backward of the thigh muscles so that they may be nearly parallel with the backbone. Thus he is able to walk when on the ground.

Further widening of the iliac crest together with an expansion of the iliac and gluteal muscles is seen in the gorilla (Fig. 5 c). This is further conditioned by the habit of sitting and walking upright on the ground. The gorilla, because of its great weight must of necessity be principally terrestrial, however it may take to the trees under certain conditions.

There is such a striking resemblance between the anthropoids and ourselves in external form and in their attitudes, also in their internal structure, particularly when studied in captivity that we are apt to overlook the radical distinction in their mode of locomotion. In man, his whole weight is poised on a very narrow pedestal in direct opposition to the erect posture. If he declined at all from it he would be forced to the earth, but for the predominance in the back and the legs of the extensors over the flexors. The position of the ape in nature is just the reverse. He hangs and moves about among the trees by means of his long and powerful arms. He is thus sustained not from below but from above where by his weight would soon bring him to earth, except for the immense power of his flexor arm muscles.

Various investigators have reported their studies of dissected material, and seem to be in general agreement that the muscle pattern of apes and man is similar the main difference being in function and thus also in comparative size. For instance the gluteal muscles in quadrumanes are small and weak. Thus we assume that it is for this reason that the apes are unable to stand erect or stand on one leg as we do whereas the real distinction is in the position of these muscles thus accomplishing a different function mainly that of leaping. Man, however does not leap well, and consequently by a priori reasoning we might assume that his glutei are small. This we know is not true. Again certain animals such as the horse cannot

SPLITHOIF ORIGIN AND DEVELOPMENT OF ERECT POSTURE

stand erect The secret of the functional difference is the position of the focal point of action In man the external surface of the short broad ilium looks outward like the acetabulum The fibers of the gluteus medius converge from a broad origin to the great trochanter the whole arrangement acts to prevent the body from sinking to one side when supported by the opposite leg It also assists the gluteus maximus and the psoas in preserving the balance forward and backward required in ordinary progression (8)

In apes the external surface of the ilium looks upward or backward while the acetabulum still looks outward as in man Thus the ilium is at right angles with the ilium which is long and narrow so that the fibers of the gluteus run nearly parallel to each other and the muscle is inserted at the end and not as in man down the outer side of the trochanter Thus the leverage arm acts to greater advantage in man aiding pelvic balance in walking and in the erect posture The glutei semitendinosus and biceps support the trunk behind and the gracilis and sartorius antagonize them in front In man the glutei and long flexors of the leg have two sets of function according to whether or not they take their fixed point of function from above or below This means that they may be used either for moving the legs by themselves or for acting powerfully upon the trunk as in locomotion The human pelvis is likewise fitted in many other ways to act as a bony anchor for the muscles that tie in the abdominal viscera, and as a base for the powerful thigh and back muscles that hold the body erect

Sir Arthur Keith has divided the evolution of the erect posture into three phases the first the hylobation or gibbon type represented by fossil remains found in Pliocene and Miocene deposits of Europe parts of which very closely resemble the modern gibbon He therefore assumes that they have come through unchanged or troglodyte stage of which the chimpanzee is the most generalized surviving member whose upper and lower limbs are developed to a more or less equal degree The gorilla also in this group however shows specialized development of the lower limbs. The third or plantigrade

stage is represented by changes principally to the lower limbs The knees thigh extended and lengthened the pelvis modified and the muscles and bones as human form We cannot fix the exact geological date and no fossil showing the transition has been found It is assumed that geological date is in Miocene or Oligocene times about 20 to 35 million years ago (Fossil man has contributed little to knowledge of when human posture evolved We know that his posture was crouching character similar to the apes. Marcellin Boule in describing the so-called Neanderthal skeleton from La Chapelle Aux Saints states the vertebral column was short and massive The first vertebrae are much more like those of a chimpanzee than those of a man The spinous processes are long lying at right angles to the axis of the vertebral column instead of inclining backward and they are not bifurcated at the end.

These peculiarities seem to indicate in the cervical region of the vertebral column a

Fig. 4. Reconstructed skeleton of *Notharctus*, found in the primates. A North American of Eocene times. (Courtesy after W. K. Gregory)

stand erect. The secret of the functional difference is the position of the focal point of action. In man the external surface of the short broad ilium looks outward like the acetabulum. The fibers of the gluteus medius converge from a broad origin to the great trochanter the whole arrangement acts to prevent the body from sinking to one side when supported by the opposite leg. It also assists the gluteus maximus and the psoas in preserving the balance forward and backward required in ordinary progression (8).

In apes the external surface of the ilium looks upward or backward while the acetabulum still looks outward as in man. Thus the acetabulum is at right angles with the ilium which is long and narrow so that the fibers of the gluteus run nearly parallel to each other and the muscle is inserted at the end and not far down the outer side of the trochanter. Thus the leverage arm acts to greater advantage in man aiding pelvic balance in walking and in the erect posture. The glutei semitendinosus and biceps support the trunk behind and the gracilis and sartorius antagonize them in front. In man the glutei and long flexors of the leg have two sets of function according to whether or not they take their fixed point of function from above or below. This means that they may be used either for moving the legs by themselves or for acting powerfully upon the trunk as in locomotion. The human pelvis is likewise fitted in many other ways to act as a bony anchor for the muscles that tie in the abdominal viscera, and as a base for the powerful thigh and back muscles that hold the body erect.

Sir Arthur Keith has divided the evolution of the erect posture into three phases the first the bylobation or gibbon type represented by the fossil remains found in Pliocene and Miocene deposits of Europe parts of which very closely resemble the modern gibbon. He therefore assumes that they have come through unchanged. The next phase is that of the great anthropoid or troglodyte stage of which the chimpanzee is the most generalized surviving member whose upper and lower limbs are developed to a more or less equal degree. The gorilla also in this group however shows specialized development of the lower limbs. The third or plantigrade

Fig. 4. Reconstructed skeleton of *Notharctus*, founder of the primates. A North American of Eocene times. (Reproduced by Courtesy of American Museum of Natural History after W. K. Gregory.)

grade stage is represented by changes confined principally to the lower limbs. The knees and thigh extended and lengthened the pelvis was modified and the muscles and bones assumed human form. We cannot fix the exact geological date and no fossil showing the transformation has been found. It is assumed that the geological date is in Miocene or Oligocene times about 20 to 35 million years ago (6). Fossil man has contributed little to our knowledge of when human posture evolved. We know that his posture was crouching in character similar to the apes. Marcelin Boule in describing the so-called Neanderthal skeleton from La Chapelle Aux Saints states that the vertebral column was short and massive. The first vertebrae are much more like those of a chimpanzee than those of a man. Their spinous processes are long lying at right angles to the axis of the vertebral column, instead of inclining backward and they are not bifurcated at the end.

These peculiarities seem to indicate in the cervical region of the vertebral column either

Fig. 5. Progressive widening of the pelvis and sacrum in Primates. a, Lemur with long narrow ilia adapted for leaping; b, Gibbon, incipient widening of iliac blade; c, Gorilla; d, Man (Reproduced by Courtesy American Museum of Natural History after W. K. Gregory)

etc absence of curves or a slight curve in direction opposite to that in modern man negating the dorsal curve as occurs in an old ape, such as chimpanzee.

The vertebrae of the other regions are not so preserved. It would seem as if the lumbar curve were less pronounced than in the major part of modern men. The portions of the sacrum which we possess point to narrow sacral transverse processes slightly arched and deeply set beneath the iliac bone. These are Simian characteristics. (1)

Thus Marcellin Boule gives account of the ancient crouching posture of one of the most primitive of prehistoric men. It may be concluded therefore that if Neanderthal man still retained a moderate crouching posture and had Simian characteristics of his skeleton 25,000 years ago that human posture as we know it today has finally evolved in that span of time; however it is possible that erect forerunners of *Homo sapiens* (e.g.

Pittdown man) may date back to upper Pliocene times around one million years ago (4). We may conclude further that the low back area together with the sacrum and pelvis remain in a state of flux because it is this portion of the skeleton which has undergone the greatest change in the synthesis of erect posture. The human skeleton as we know it today may be the best adaptation for the purpose to which it is being put, however it is axiomatic that nature develops by trial and error and that future millennia will produce a structure better adapted to the stresses and strain which the erect posture entails.

CONCLUSION

Human posture is shown to have evolved through a series of progressive changes beginning with the prehistoric Devonian fish, 350 million years ago. Changes occurred which allowed the ancient amphibians some 50 million years later to become land dwellers. Because

of poor adaptation to terrestrial locomotion their efforts were probably limited simply to obtaining food with little attempt made to move for any distance

Walking continued to be cumbersome in the ancient reptiles whose limbs were widely spread apart and not yet well adapted for land use. However progress was made by evolutionary changes and there evolved a creature actually able to run on land. From this *Cynognathus* which existed 175 million years ago has evolved the more highly developed *Notharctus* an arboreal monkey like mammal.

The *Notharctus* was one of a great group of primitive primates and as such may be considered a representative progenitor of the order to which man belongs. The ability to climb trees was possessed by this animal and later by other lemurs, monkeys and apes. The only ape able to walk upright on the ground is the gibbon an East Asiatic tree living descendant of the first family of man like apes. The skeleton of this ape begins to appear almost human in type. Nature first endowed this ape with the ability to walk by up-ending one tower of the suspension bridge to which the shoulder and pelvic girdle together with the spine may be compared and balance it on its rear tower represented by the pelvic girdle. The ability to walk upright was evolved from the habit of sitting upright and by the habit of brachiating or swinging from limb to limb. The ability to walk has been perfected in the human through modification of the entire skeleton but principally the pelvis and lumbo-sacral spine. It is true that certain apes can walk upright however this gait may not be natural for them because the pelvis is not mech-

anically suited for such progression. The muscle pattern of ape and man is similar yet there is a difference in function and in comparative size and a difference in the focal point of action of the gluteal muscles which is the secret of human ability to walk. In the ape the external iliac surface points backward at right angles to the acetabulum rather than externally or outward as in the human.

Thus human posture was evolved by progression from water onto land then into the trees and to the ground again and as this progress was made the skeleton was conditioned to the habits of the animal or the uses to which it would be put. Since man is the culmination of nature's efforts over many millions of years it may be inferred that the erect or orthograde posture is the ideal means of terrestrial progression and that no further change will occur. However in the words of Professor William K. Gregory evolution bears no evidence of a beginning and no prospect of an end thus we may hope that a more perfect creature is yet to evolve.

MALIGNANT LYMPHOMA

The Value of Radical Surgery in Selected Cases

C. ALEXANDER HILLWIC, MD, Wacht, K. C.

SURGERY as a therapeutic measure in malignant lymphoma has been generally abandoned and has been replaced by radiation therapy because the disease is regarded as essentially systemic. Recently, however, Call expressed the belief that radical surgery has a definite place in the treatment of malignant lymphoma. In his series of 48 patients with the disease sufficiently localized to permit radical surgical excision 19 survived two to three times longer than identical cases treated by radiation. From the Memorial Hospital, New York, Sugarbaker and Craver reported a 5-year survival rate in 24 per cent of patients with malignant lymphoma subjected to early surgical treatment.

During the past twenty years I have not infrequently noticed that sufferers from malignant lymphoma lived 5 years and longer after surgical removal of a single tumor and belied the gloomy outlook which had predicted from the microscopic section. This discrepancy between occasional long survival period after operation and the discouraging viewpoint of most surgeons regarding malignant lymphoma prompted me to review all primary lymphoid malignant tumors which have passed through the Pathological Department of St. Francis Hospital from January 1926 to December 1945. 34 cases of malignant lymphoma were examined in our laboratory. While histologic slides were available for personal study from all these cases only 110 cases were used for this analysis because they had complete clinical records and had been followed up for a sufficient length of time to be of value. The material included in this survey comprised autopsies and all surgical specimens from a total of 110 patients.

Records were complete to the day of death for 65 patients and 42 patients are still alive for period of 5 years or longer after the histologic diagnosis of malignant lymphoma had been established.

CLASSIFICATION OF MALIGNANT LYMPHOMA

In cases of lymphoid tumors the difficulty in distinguishing between an inflammatory and a neoplastic tumor and the uncertainty of correlating histologic structure and clinical course is familiar to every pathologist. Many surgeons and pathologists call all lymphoid malignant growths simply lymphosarcoma and they point out the possible transformation of one process to another. They believe that these processes are not only genetically related but that fundamentally they are merely phases of the same disease. I wing on the other hand in this on a rigid application of simple histologic principles in the classification of lymphoid tumors even at the risk of carrying the anatomical distinctions too far.)

During recent years three attempts have been made to classify lymphoid tumors. I have accepted the principles of the Lymphatic Tumor Registry and distinguished between reactions and tumors of lymphocytic and of reticulum cell origin, those with and without leucemia. Murray and Broders described four grades of lymphosarcoma based on the degree of cell differentiation. They employed similar criteria as used in grading of epithelial malignant growths and believed that the histologic grade in primary lymphosarcoma bears a definite relation to the time of survival following operation.)

In 1914 Call and Malory proposed a classification not regarding anatomical distribution of the lesion and blood manifestations. From their analysis of 445 cases they concluded that nothing in the histologic character of an individual lesion will permit a reliable predic-

Fig 1. Inoperable neck tumor in 56 year old male. Biopsy by incision into a tumor which is firmly fixed to surrounding structures is not advisable. Aspiration biopsy revealed typical lymphoblastoma. Initial response to roentgen treatment good. In our material, one out of three noninflammatory neck tumors was a malignant lymphoma.

Fig 2. Localized reticulocytoma of mandible in 5 year old girl. Total removal of lower jaw without radiation resulted in cure. No evidence of disease today 10 years after operation.

as to the distribution of the process in other parts of the body nor can it be determined whether leucemia is present or not by histologic examination of a lesion.

The same authors found a great constancy of the reacting cell types in biopsies of the same case taken at different times: in only 23 per cent did the lesion become less differentiated in appearance. As to the possibility of histologic distinction of the different types in routine biopsy material they could apply their method easily in 94 per cent. Gall and Mallory's classification which is fundamentally cytologic has the advantage of conforming with the accepted usages of oncology and it has more than academic value in the field of malignant lymphoma since a reasonable degree of correlation could be demonstrated with the clinical course of the disease.

The cell types making up the various subgroups of malignant lymphoma correspond to the different stages of cell development as found in normal lymph nodes. A knowledge of the normal cytology of lymphoid tissue is therefore necessary. According to Maximow the supporting stroma in lymphoid tissue consists of a framework of argyrophilic fibers intimately connected with an undifferentiated cell syncytium mesenchymal in nature. These undifferentiated reticular cells are large, stellate or spindle shaped and have an abundant

cytoplasm and a pale oval nucleus. They are not phagocytic in character and possess unrestricted potentialities for differentiation. The lymphatic sinuses of the lymph nodes are lined with specially differentiated reticular cells which have been termed by Siegmund (1925) littoral cells. These cells are phagocytic and are entirely different from the endothelial cells lining ordinary blood and lymph vessels. From these fixed littoral cells clasmotocytes and the monocytes of the circulating blood are derived; these cell types are not only closely related, but are indistinguishable from each other. Their outstanding characteristic is their phagocytic property. In the germinal center of lymph follicles, lymphocytes are formed from the reticular cells. The immediate descendants of the reticular cells appear as lymphoblasts. The latter are the mother cells of the mature small lymphocyte. In this line of differentiation the phagocytic properties are lost and the resulting cells no longer store vital dyes. Further differentiation is restricted though lymphocytes may give rise to plasma cells as a result of unknown stimuli.

True mesenchymal reticulum is found in the malpighian corpuscles of the spleen in bone marrow and as undifferentiated cells of the connective tissue as well as in lymph nodes. In these locations also the reticular cells possess the ability to differentiate into the various described cell types.

Adhering to Gall and Mallory's general outline but substituting some of their unfamiliar terms with those used by the Lymphatic Tu-

Fig. 3. Axillary lymphocytoma consisting of 5 nodes in 8 year old male. Removal of all tumors and postoperative radiation 8 years ago. Patient is living and well 1 present.

mor Registry (Callender) I divided my material of primary lymphoid tumors into 8 groups. The number of cases encountered in this survey of 130 malignant lymphomas were as follows:

	Cases
Reticulocytoma	6
1. Giant cell reticulocytoma	5
2. Monocytoma	1
3. Hodgkin's disease	26
4. Lymphoblastoma	44
5. Lymphocytoma	34
6. Follicular lymphoma	
7. Plasmacytoma	
Total	30

In our experience most malignant lymphomas fall into four groups, namely reticulocytoma, Hodgkin's disease, lymphoblastoma, and lymphocytoma. The percentage of the other four groups we found varies between 0.8 and 3 per cent.

Tumors composed of highly undifferentiated reticular cells are called stem cell lymphoma by Gall and Mallory while we prefer the term of the Registry reticulocytoma. Tumors made up of more mature phagocytic cells corresponding to littoral cells, clasmatocytes, and monocytes are designated as clasmatocytic lymphoma by Gall and Mallory, but as monocytoma by us. The group of tumors called Hodgkin's sarcoma by Gall and Mallory is apparently the same which Foot calls pleomorphic lymphosarcoma and for which we

Fig. 4. Breast with large lymphoblastoma in 3 year old female. Metastases to axillary and abdominal nodes at time of admission. In spite of intensive radiation therapy death occurred 3 months after admission.

propose the term giant cell reticulocytoma. While there are authentic cases reported in which Hodgkin's diseases after a comparatively benign course becomes transformed into a rapidly progressive tumor in our material the cases of giant cell reticulocytoma have shown their characteristic clinical and morphologic behavior from the onset.

The justification of subdividing the malignant lymphomas into 8 distinct groups rests on the constancy of the cell type in an individual case. Sixteen patients of our series had biopsies on two or more occasions or specimens were available from both biopsy and subsequent necropsy. Of our 30 autopsy cases microscopic sections of all involved organs were studied. In about 82 per cent the original histologic structure was maintained while in only 18 per cent the lesion became less differentiated. This degree of dedifferentiation must be expected in any group of malignant tumors followed over a longer period of time. The occasional transition from one form to another supports the view that these tumors are essentially of common origin but does not invalidate the practical application of Gall and Mallory's classification.

CLINICAL OBSERVATIONS

Incidence In comparison with other types of cancer malignant lymphoma is not common. Between January 1925 and December 1945 699 lymphoid tumors were submitted to our laboratory for histologic diagnosis of

Fig. 5. Mediastinal lymphoblastoma compressing trachea and both main bronchi. Sudden death by suffocation. X ray therapy may prevent sudden death in these inaccessable tumors however life expectancy of different tumor types is seldom prolonged by radiation

Fig. 6. Intrapulmonary malignant lymphoma. Surgical removal of entire lobe eradicated the tumor as shown by autopsy

which 234 proved to be malignant lymphomas. They represented less than 5 per cent of all cancers examined during the 21 year period. The average number of malignant lymphomas seen in our laboratory during an average year is therefore less than twelve. Our material came from 57 surgeons and the largest number of lymphoid tumors submitted by a single surgeon was 18 while 53 physicians had only one case each.

Age. As the age of onset we have listed the age at which the first relevant symptom was noted. For the entire group the average age was 44.7 years, about 10 years lower than that for the epithelial types of cancer (53.8 years). The average age was 5 years higher in females (45.5 years) than in males (40.8 years). In general malignant lymphoma is rare before the age of 20 years and after the age of 70. Our youngest patient was 4 months old (lymphoblastoma) and our oldest 84 years (monocytoma).

While in Gall and Mallory's series Hodgkin's disease had a tendency to appear nearly a decade earlier than any other form of lymphoma, in our material the age of patients with Hodgkin's disease was only slightly lower than in the entire series namely 42.3 years. The most common period of life when malignant lymphoma became evident was the fourth and fifth decades. Two types lymphoblastoma and lymphocytoma occurred in the first two decades with significant frequency 14 and 10 per cent respectively. Below the age of 40 there were 23 per cent of reticulocytomas and 25 per cent of follicular lymphomas.

Sex. It is generally stated in the literature that malignant lymphomas show a predilection for the male sex. Gall and Mallory found a definite predominance of men over women (2.2 to 1). Sugarbaker and Craver reported

Fig. 7. Resection of stomach. 11th primary Hodgkin's disease. 60 year old male. Complete removal of disease. No other foci found at autopsy.

Fig. 9. Surgical specimen of giant reticulocytoma of cecum in 67 year old female, no postoperative radiation. Clinical cure since operation 6 years ago.

the same characteristic sex distribution namely a ratio of about 7 to 3. In our own material on the other hand the frequency was found to be almost equal namely 3 males to 2 females.

Primary site. Cutler states that in cases in which clinical examination discloses cervical lymph nodes invaded by lymphosarcoma the presence of a primary lesion in the pharynx or nasopharynx should be suspected and Coutard advises that these areas should be irradiated even when a primary focus cannot be demonstrated. In our material, which includes complete autopsy studies in 30 cases, an extranodal primary focus of the disease

could be demonstrated in only one third of all cases. In 26 cases the primary focus could be reasonably assumed to arise in one of the cranial structures with the tonsils and nasopharynx as the most common sites. In 19 cases the disease arose apparently in the gastrointestinal tract (stomach 5 ileum 4 appendix 2 rectum 8 cases). In the remaining 6 cases primary sites were widely scattered: 1 in bone, thymus, lung, ovary and skin.

Two thirds of the entire series never had what could be supposed to represent an extranodal primary focus. In these the first and only subsequent evidence of disease was confined to lymph nodes until widespread dissemination took place. Our own experience therefore conforms with that of Sugarbaker and Craver that malignant lymphoma is a disease which in the majority of cases begins, and runs its early course in the lymph nodes alone.

The site of the first lymph node involvement is of interest. In 40 per cent of the cases the lymph nodes of the neck were first involved, the axillary nodes in 9 per cent, the inguinal glands in 13 per cent, and the abdominal nodes in 4 per cent. Mediastinal nodes were enlarged in 8 per cent. In less than 2 per cent of the patients the disease appeared to involve almost the entire node system simultaneously.

Fig. 8. Lymphocytoma of jejunum in 53 year old female. Resection as not followed by radiation. No recurrence or other manifestations of disease in following 7 years.

TABLE I.—FIVE YEAR SURVIVALS AFTER RADICAL SURGERY WITHOUT RADIATION

No.	Age	Sex	Location	Histologic type	Follow-up
1		M	Tonsil	Reticulocytoma	Living and well, 80 yrs.
2	5	F	Jaw	Reticulocytoma	Living and well, 10 yrs.
3	67	F	Cecum	Giant cell reticulocytoma	Living and well, 6 yrs.
4	60	M	Inguinal	Hodgkin's disease	Living and well, 9 yrs.
5	55	F	J. Junction	Lymphocytoma	Living and well, 7 yrs.
6		M	Neck	Lymphocytoma	Living and well, 12 yrs.
7	0	F	Appendix	Lymphocytoma	Living and well, 5 yrs.
8		F	Skin (breast)	Lymphocytoma	Living and well, 7 yrs.
9		F	Anal	Lymphocytoma	Living and well, 6 yrs.
10	26	F	Supraclavicular	Lymphocytoma	Living, diseased, 0 yrs.
11	40	M	Neck	Lymphocytoma	Living and well, 15 yrs.

In addition to the primary sites of involvement, numerous organs may subsequently become involved either as a result of lymphatic or hematogenous metastasis or by direct extension. The spleen was palpable in 23 per cent of our cases, liver enlargement was recorded in 6 per cent. Roentgenologic evidence of infiltration of lungs and pleura was present in 21 cases. Metastatic involvement of the skin occurred in 16 per cent and of the bones in 12 per cent.

Evidence of presumably secondary foci in the gastrointestinal tract was obtained in 27 cases. The rapidity with which lymphoma advances is readily understood when one con-

siders that the average duration of life from onset of the disease until death was only 26 7 months.

Systemic symptoms Chill, fever, weight loss and weakness rarely appeared before the disease had become far advanced. The general mildness of the symptoms early in the disease is evidenced by the fact that the average interval between first symptoms and hospital admission was 10 3 months. Temperature of 101 degrees and higher occurred at some time during the course of the disease in 40 per cent of the lymphocytomas and 42 per cent of the lymphoblastomas. In 55 per cent of Hodgkin's disease intermittent fever was recorded. This

type of fever was also frequent in giant cell reticulocytoma.

Blood findings. In contradistinction to Hodgkin's disease in whom anemia usually develops early (11%) the other types of lymphoma maintained good hemoglobin values for some time. On admission 61 per cent of our patients showed hemoglobin readings above 80 per cent and only 36 per cent of the cases had less than 70 per cent hemoglobin. As a result of advancing disease very definite blood changes took place. Only 32 per cent of the patients at this time had hemoglobin values higher than 70 per cent. In 16 per cent of the higher series the red cell blood count was less than three million. Profound anemia was recorded most often in lymphoblastic and lymphocytic types (15 and 11% respectively) associated with leucemia.

A leucocytosis exceeding 12,000 per cubic millimeter on admission was found in 13 per cent of the lymphocytoma cases and in 10 per cent of lymphoblastomas. The same count was noticed in 11 per cent of Hodgkin's disease. Leucopenia with white cells numbering less than 5,000 cells per cubic millimeter was noted in about 20 per cent of lymphoblastoma and lymphocytoma and half as often in Hodgkin's disease. Monocytes in excess of 10 per cent were recorded in all cases of monocytoma and in some cases of Hodgkin's disease. In the latter eosinophilia was not a prominent feature. Atypical cells, either unidentified or blast forms appeared in the peripheral blood of 15 per cent of the cases of lymphoblastoma and 13 per cent of those with lymphocytoma. In the other subgroups these abnormal cells were infrequent.

Blood pictures characteristic of leucemia occurred at some time during the course of the disease in 26 per cent of the cases with lymphocytoma and in 15 per cent of those with lymphoblastoma. They were absent in reticulocytoma and infrequent in the remaining types. Individual patients showed true leucemia at intervals, then subleukemic or aleukemic blood pictures. Of the patients with positive blood findings 132 per cent were nonleukemic when first observed, but developed leucemia later in the course. 17 per cent were leukemic at the initial observation but

showed normal blood pictures prior to death and 11 per cent were leukemic at the beginning and at the end of the disease, but were nonleukemic in the interval. In only one half of the leukemic patients was the blood picture entirely constant throughout the course of the disease. Of the patients in whom a leukemic or subleukemic picture was superimposed none survived the 5 year period following biopsy. The duration of disease in these cases varied between 6 weeks and 4 years, its average being 151 months against 267 months for the entire series.

DURATION OF DISEASE

The duration of the disease depends to a surprising degree on the cytologic character of the underlying lesion. Four types of malignant lymphoma, namely lymphoblastoma, reticulocytoma, giant cell reticulocytoma and monocytoma offer a relatively poor prognosis with an average duration from 33 to 11.8 months. lymphocytoma and Hodgkin's disease run a comparatively slower course with averages of 36 and 38 months, while follicular lymphoma and plasmocytoma offer a much better outlook lasting in the average 4.8 and 4.3 years respectively. For the entire series of lymphoma the average duration was 267 months. In even the most malignant types occasional instances of unusually long survival are met. These are least frequent in lymphoblastoma, monocytoma, and giant cell reticulocytoma. While only one giant cell reticulocytoma, 3 reticulocytomas, and 7 lymphoblastomas survived longer than 5 years, there were 17 lymphocytomas who did not show any sign of the disease 5 years and longer following operation.

The group prognosis is altered definitely by the presence of blood findings characteristic of leucemia. Patients with leucemia have a life expectancy of about 1 year less than those without leukemic manifestations. A less important factor in our series was the age of the patients at the onset of the disease only in lymphoblastoma and Hodgkin's disease was the life expectancy shorter in the few cases which occurred before the age of 10 years.

Of all 130 patients, 32 or 24.6 per cent, have survived 5 years or longer. Ten per cent

of our patients survived eight years or more. Twenty three or 17.2 per cent, of the entire series are apparently cured. 7 died more than 5 years after treatment was begun and 2 are living with active disease still present. The longest duration recorded in our series was 20 years the patient still being alive after removal of a reticulocytoma involving a tonsil.

TREATMENT

In general malignant lymphoma is extremely radiosensitive, and it is not surprising to observe a bulky tumor mass regress to half its size after a few days of treatment and completely disappear within a week (Sugarbaker and Craver). In occasional cases in which large masses are situated in vital locations inaccessible to surgical intervention—for instance intrathoracic tumors—radiation may be life saving and may avert sudden death. On the other hand most observers (Minot and Isaac, Sugarbaker and Craver) agree that roentgen therapy does not seem to prolong the average duration of life.

Failure to respond initially to x ray therapy was rare in our cases of Hodgkin's disease, follicular lymphoma, and lymphocytoma, while more than one half of the reticulocytomas and 40 per cent of the lymphoblastomas failed to show any evidence of improvement following irradiation.

Only 2 of 40 patients survived the 5 year period following irradiation alone after the diagnosis had been made by biopsy. One patient had a lymphoblastoma, the other a lymphocytoma.

Since x ray treatment has become the standard treatment for malignant lymphoma once the diagnosis has been established a comparison of patients treated in this manner with those who have been treated solely with surgery is extremely difficult.

The pessimistic view that surgery as a therapeutic measure in malignant lymphoma is contraindicated presumably on the basis that the disease is essentially systemic is contrary to our experience. First it is noteworthy that 10 per cent of our autopsy cases certainly were not systemic in character but showed single localized lesions accessible for surgical excision. Second the long survivals in our

series following operation suggest that in certain cases of malignant lymphoma with localized lesion patients may be treated more successfully by surgical procedure than by any other means.

Surgical therapy was initially employed in 67 cases with the intention of effecting a cure and often in ignorance of the true nature of the tumor. Of the 63 patients who survived the operation 21 received no other form of therapy, while 42 received postoperative external radiation regardless of the absence of clinical symptoms.

Of the 21 patients who underwent surgical operations and who did not receive radiation therapy 12 survived 5 years or longer and none shows at present any evidence of disease. In this group the following types of malignant lymphoma were represented: 2 reticulocytomas, 1 giant cell reticulocytoma, 1 Hodgkin's disease, and 9 lymphocytomas.

In 40 instances, radical removal of a single focus of disease was followed by adequate radiation. Eighteen of the 40 patients survived and 9 are at present without clinical evidence of the disease. There were 6 lymphoblastomas, 7 lymphocytomas, 1 follicular lymphoma, 1 plasmacytoma, and 2 Hodgkin's diseases in this second group.

From these observations it must be concluded as long as malignant lymphoma is confined to an accessible single mass that there is an excellent chance for obtaining a cure by complete removal of the primary focus.

CONCLUSIONS

1. A comparative clinical pathologic study of 130 cases of malignant lymphoma is reported.
2. Following Gall and Mallory's cytologic classification 8 types of malignant lymphoma were distinguished corresponding to different degrees of differentiation of their component cells.
3. There was a close correlation between the histology and life expectancy of the different subgroups.
4. The average duration of disease was found to be 26.7 months for the entire series. It varied in the different histologic types between 3 months and 4.8 years.

5 Due to its striking initial effect on lymphoma, radiation therapy may occasionally save a life when the tumor is located in a vital part of the body inaccessible for surgery but it will seldom prolong the life expectancy inherent to the histologic type of lymphoma.

6 Early surgical removal of a primary focus of disease offers the best chance of cure in malignant lymphoma. In our entire series 24.6 per cent of the patients survived 5 years or longer regardless of postoperative radiation. In 21 patients with a single primary focus radical surgery alone was used and 12 of the 21 patients survived from 5 to 20 years.

DIGESTION OF LIVING TISSUE BY THE HYPERACID STOMACH

An Experimental Study

PHILIP B. PRICE, M.D. and TUNNIE F. LEE, M.D., Salt Lake City, Utah

IN a recent publication we showed that living autogenous organs and tissues of all sorts are completely digested in from 1 to 6 weeks when they are deeply implanted in the canine stomach. Those experiments were carried out on dogs with normal gastric secretions. In the present investigation we have repeated the experiments using the same technique of implantation, but we have given these animals daily postoperative injections of histamine in order to study the effects of hyperacidity upon the process of autodigestion.

Sixty-six healthy adult dogs were used. Under pentobarbital sodium anesthesia with aseptic technique, various organs and tissues of the body were implanted through large windows, usually in the anterior wall of the stomach. Care was taken not to compromise the circulation of the implants. Beginning 24 hours after operation each animal received daily intramuscular injections of histamine dihydrochloride. The histamine was mixed with beeswax and mineral oil after the technique of Hay, Varco, Code, and Wangenstein. Uniform daily doses of 30 milligrams of histamine base were administered irrespective of the weight of the dogs.

The animals were observed closely following operation. Food ("purina dog chow") and water were allowed *ad libitum*. Periodic measurements were made of weight, temperature, hematocrit, hemoglobin, blood cell counts and plasma proteins. At suitable intervals the implants were explored surgically or the animals were sacrificed and examined, blocks being cut for microscopic study. These examinations were usually made 24 hours after the last in-

jection of histamine. At the time of implantation before the animals had received histamine, and subsequently whenever the stomach was opened at operation or autopsy, samples of fasting gastric contents were secured for analysis. The dogs used in these experiments averaged 19.3 units of free acid and 55.1 units of combined acid before histamine was injected; after histamine the samples averaged 91.4 units of free acid and 33.1 units of combined acid.

EXPERIMENTS

1 Digestion of living omentum The corrosive effect of hyperacid gastric juice upon the omentum was pronounced. Characteristic fibrosis and granulation tissue response occurred but were ineffectual barriers to the digestive process. Omental patches covering large gastric windows had irregular necrotic craters after 2 weeks, and one such patch perforated on the twentieth day with resultant general peritonitis. Large tongues of omentum implanted deeply in the lumen of the stomach were more rapidly digested in these dogs than were similar preparations in normal animals.

2 Digestion of living intestine Implants of intact jejunum, appendix, and cecum were quickly digested by the hyperacid stomach. Two out of 6 animals died within 24 hours of hemorrhage from the rapidly eroding intestinal wall. Perforation of the implant usually occurred in less than 1 day, and much of the implant had disappeared entirely by the eighth or tenth day. Histologic changes were observed similar to those previously reported for normal dogs, but the process of inflammation, necrosis, and digestion appeared to be far more acute in the present series.

3 Digestion of living organs An implanted lobe of liver showed partial erosion after 3 days and digestion nearly to the level of the gastric wall within a week. In normal dogs complete

From the Department of Surgery, University of Utah Medical School, Salt Lake City.

Aided by grants from the Doctors' Research Fund and the Rockefeller Field Research Fund of the University of Utah School of Medicine.

digestion of the hepatic implant was not obtained until the end of the fourth week.

The gall bladder was implanted in 3 hyperacid dogs. After 24 hours (that is, 24 hours after histamine was started) the gall bladder wall had perforated and was partly digested after 3 days the implanted portion had almost entirely disappeared leaving a large ragged fistula between the stomach and the remainder of the gall bladder.

The tail of the pancreas was implanted in 2 dogs. In both instances complete digestion of the implant occurred within 3 days.

The lower pole of the spleen was successfully implanted in 3 animals. This organ was likewise digested rapidly by the hyperacid stomach partial digestion occurring in 2 days and complete digestion to the level of the stomach wall after 3 days. A similar degree of digestion was not observed in normal animals before the nineteenth postoperative day.

The superior pole of the left kidney was satisfactorily implanted in 3 dogs. All of the implants showed relatively rapid digestion as compared with digestion of similar implants in normal dogs. One animal, sacrificed on the nineteenth day showed loss of the entire upper pole with exposure of the calyces to gastric juice.

4. *Digestion of living connective tissue.* Cartilaginous ends of ribs were fully digested away after 3 days of hyperacidity (4 days after implantation).

Pedicle skin flaps from the anterior abdominal wall likewise suffered relatively rapid digestion as did free skin grafts growing on intra abdominal serosal surfaces.

When large gastric windows were sewed to the parietal peritoneum of the anterior abdominal wall progressive erosion of the tissues occurred. These ulcerations eventually extended through muscle and fascia forming abscesses. One dog died on the fourth postoperative day with a large abscess beneath the anterior rectus fascia. Another dog died on the sixth postoperative day with a subcutaneous abscess which extended to the axilla.

5. *Digestion of living gastric tissue.* Artificial ulcers were produced in the stomach by cutting away round or oval areas of mucosa. The defects exposed the outer layers of the

stomach wall to the digestive action of the strongly acid gastric juice. These lesions all showed progressive erosion of both mucosal margins and ulcer base. One dog died of perforation and peritonitis 3 days after operation and 2 days after the histamine was started. Another dog which was sacrificed on the seventh postoperative day was about to perforate.

Pedicle flaps of gastric wall turned into the lumen of the stomach, as described in our previous article, were digested in 3 to 6 days. When these flaps were denuded of mucosa at the time of implantation complete digestion occurred in less than 3 days.

OBSERVATIONS

Daily injections alone of 30 milligrams of histamine base will cause spontaneous ulcerations in the previously healthy stomach and duodenum. Hay and his associates found that of 12 dogs so injected 8 developed duodenal, and 3 developed gastric, ulcers. These animals received an average of 24 doses of histamine although 1 dog had a large gastric ulcer and a nearly fatal hemorrhage after only 4 injections. Another died after 7 injections of multiple perforated duodenal ulcers. Other investigators have obtained similar results. Crandall in this laboratory injected 10 dogs (4 normal dogs, 4 with Finney pyloroplasties and 2 with gastroduodenostomies) and obtained ulcers—gastric, duodenal, or both—in all of them. The duration of histamine therapy in this control series was from 8 to 44 days. It was not determined how soon the ulcers developed but one of the dogs died on the eighth day as a result of a perforated duodenal ulcer and peritonitis.

In our larger series, where the animals had operative implants and subsequent injections of histamine there were only 5 instances of independent ulcer formation at a distance from the implant. This relatively small incidence of ulcer production is explained by the short duration of the experiments. Our dogs died or were sacrificed, on the average, 4.9 days after histamine therapy was instituted. Duodenal ulcers were observed in 4 dogs which had received histamine 5, 5, 4, and 3 days, respectively and 1 dog which had received histamine

injections for only 3 days showed both gastric and duodenal ulcers. None of them had perforated. On the other hand 2 dogs which had received histamine for 19 days showed no evidence of spontaneous ulceration.

Pronounced deterioration of health was noted in about two-thirds of our animals. Loss of appetite was a constant feature. Weight loss for the entire group averaged 2.77 per cent of the original body weight per day. Hair lost its gloss and was shed freely. Vomiting was conspicuous in 5 cases.

Most of the animals developed a moderate degree of anemia. Hematocrit determinations for the entire series fell from an average of 47.0 to 38.0, hemoglobin from 17.2 grams to 13.7 grams, and red cell counts from 6,330,000 to 4,824,000. Total plasma proteins showed relatively little change; however, the preoperative average being 6.36 grams as compared with a final average of 6.18 grams. Gross bleeding from the implant was a common finding; 9 of the animals were seen at autopsy to have had large, perhaps fatal hemorrhages into the gastrointestinal tract.

In our previous report on digestion of living tissue by the normal stomach it was observed that "a number of our animals appeared toxic; some were quite ill; in fact, during the period of necrosis and digestion of the implants but these animals recovered full health after the necrotic tissue had disappeared. This phenomenon was observed particularly after implantation of intestines, gall bladder and solid organs." This "toxicity" appeared to be even more pronounced in the present series. Elevation of temperature was frequently seen. The white blood cell count rose from an average of 10,020 to 19,015.

Histologic examination of the margins of implants showed that proliferation of gastric epithelium was feeble or absent, and in some instances there was progressive autodigestion of the gastric wall and extension of the area of erosion. This picture was in striking contrast to that which was seen in the normal stomach where vigorous epithelial proliferation across the base of the implant was the general rule.

SUMMARY AND CONCLUSIONS

An experimental study has been carried out in which living autogenous organs and tissues of various sorts were implanted in the stomachs of dogs. Following implantation the animals received daily injections of histamine in beeswax in order to produce a high degree of hyperacidity. Results of these experiments have been compared with those of a similar series of implantations in stomachs not stimulated by histamine injections.

The implants were all digested. The rate of digestion by the hyperacid stomach greatly exceeded that shown by the normal stomach. Tissue reactions to the corrosive process were also more violent.

Only a small proportion of the animals receiving histamine developed spontaneous ulcers at a distance from the implant, presumably because the experiments were too acute. In a control series 10 dogs which received more prolonged histamine therapy all developed gastric or duodenal ulcers.

Most of the dogs receiving histamine showed deterioration of general health.

Some of the implants bled grossly during the process of digestion and virtually all of the animals with implants developed at least a moderate degree of anemia.

Evidences of toxicity were pronounced during the period of digestion of the implants.

No living tissue, not even gastric epithelium itself, appeared to be immune to digestion by the hyperacid stomach. Fibrosis and granulation tissue occurred in some of the implants, but seemed to be ineffectual barriers to the corrosive action of very acid chyme.

This investigation supports the results of our previous study and justifies the general conclusion that living organs and tissues of all sorts are susceptible to gastric digestion, and that hyperacidity increases the rate of that digestion.

ADOLESCENT PRIMIGRAVIDA

HERBERT E. SCHMITZ, M.D. F.A.C.S., and JANET E. TOWNE, M.D., F.A.C.S.,
Chicago, Illinois

LABOR at either extreme of the woman's reproductive life is considered by many physicians to be fraught with additional hazards. That this is true in the elderly primigravida has been stated by numerous authors. The young primigravida however receives little attention in our present day texts. Greenhill (2) in the eighth revision of Dr. DeLee's text devotes the following paragraph to its consideration: "Labor in young primipara shows little variation from the usual. Eclampsia, premature delivery, atonia uteri, and breech presentation are slightly more frequent and there is a slight increase in perineal lacerations and fetal mortality. Labor is shorter somewhat easier and there is less hemorrhage. The pelvis is larger than one would expect. If this be true, there is no cause for alarm when an adolescent mother presents herself for prenatal care. Labor should be conducted with the same precaution and alertness as is customary but meddling midwifery under the guise of assistance, precipitated by the belief that catastrophe awaits the young mother is to be avoided. That we might aid the accoucheur in maintaining his equanimity while practicing that greatest of virtues necessary for the successful management of childbirth, namely watchful expectancy, this study was undertaken."

MATERIAL

At St. Vincent's Infant and Maternity Hospital, a unit of the Department of Obstetrics and Gynecology of Loyola University Clinics, the percentage of adolescent primigravida is high due to the number of unwed mothers cared for. This circumstance afforded an excellent opportunity to assemble 200 consecutive cases of primigravida 17 years of age or under (Table I).

From the department of Obstetrics and Gynecology, Loyola University School of Medicine.

Read at the Twenty-fourth Annual Fall Clinical Conference of the Kansas City Southwest Clinical Society, Kansas City, Missouri, October 7, 8, 9, 1946.

TABLE I — AGE INCIDENCE

Age groups years	No. cases
13	3

15	0
16	27
17	66
Total	99

The majority of these patients report to the prenatal clinic early in their pregnancy and during the last 2 lunar months are sequestered in the institution, their prenatal care must, therefore, be considered adequate. The deliveries are managed by the resident obstetrician under the supervision of the authors. It is our custom to perform mediolateral episiotomy in all cases and the second stage of labor is terminated by elective outlet forceps operation. Pudendal block or caudal anesthesia was employed in all cases. The third stage of labor is managed by administering intravenous ergotrate with the delivery of the anterior shoulder.

TWELVE YEAR OLD GROUP

Although precocious pregnancy reports appear in the literature they are too rare to merit consideration at this time. The youngest patients in our group as shown in Table II were 12 years of age.

Harris in 10,000 cases at Johns Hopkins, had only 2 cases of pregnancy in patients of this age. Williams had 3 cases of pregnancy in 12 year old patients. This infrequency occurred in spite of the fact that their clinic was in an area populated heavily with negroes who presumably mature at an earlier age. All of our patients were white. The average length of labor for our 3 patients was 13 hours, 33 minutes for the first stage, 62 minutes for the second stage, and 7 minutes for the third stage. There were no complications, morbidities, nor morbidities among these 12 year old mothers.

In this series 1 infant expired 12 hours after delivery which was complicated by prolapse of the umbilical cord.

stage averaged 52 minutes. In 1 case the cord prolapsed and in spite of the fact that the infant was resuscitated it died 12 hours later of respiratory complications. In the patient having a 2 hour 7 minute third stage a manual removal of the placenta was done.

FOURTEEN YEAR OLD GROUP

In the 14 year age group (see Table IV) there were 6 patients with an average length of labor of 31 hours and 50 minutes for the first stage 42 minutes for the second stage and 7 minutes for the third stage. The average time of the first stage was increased because of 1 case of prolonged labor. The first stage in this instance lasted 66 hours. The labor terminated spontaneously with the birth of a living infant. The episiotomy however became infected. There was 1 stillbirth of a

In this series there was stillbirth of monstrosity and stillbirth of monstrosity and infected episiotomy following the case of prolonged labor.

FIFTEEN YEAR OLD GROUP
In the 15 year age group of 27 cases the individual length of labor is not listed but Table V gives the average length for each stage

TABLE V.—DURATION OF LABOR
Fifteen year old group (27 cases)

Total No. cases	Average length first stage	Average length second stage	Average length third stage
27	hr 3 min	45 min	16 min.

COMPLICATIONS

- Prolonged labor 3 cases
- Neonatal death (Congenital heart defect 8th postnatal day) 1 case
- Mortality 1 case
- Retained placenta postpartum hemorrhage 3 cases
- 1 case

The average for the first stage was 13 minutes for the second stage 46 minutes and for the third stage, 16 minutes. There were 2 cases of prolonged labor each with a first stage of 28 hours. One necessitated a forceps rotation because of a transverse arrest the other terminated spontaneously. The 1 morbid case in this group was due to an upper respiratory infection the other was unclassified. There was 1 neonatal death the infant succumbing on the eighth postpartum day because of a congenital heart defect. One patient had a retained placenta which was removed manually after 3 hours and 43 minutes. The blood loss amounted to 950 cubic centimeters.

SIXTEEN YEAR OLD GROUP

Labor in the 66 patients in the 16 year age group averaged 13 hours 26 minutes for the

birth The third stillbirth resulted from prolapse of the cord The 1 cesarean section in our entire group was due to cephalopelvic disproportion The mother had a 12 hour test of labor and as a result developed an endometritis and is listed as a morbid case. The 5 other morbidities were due to mastitis upper respiratory infection right lower lobe pneumonia, cystitis and 1 not classified. There was 1 set of twins in this group and in 1 case a midforceps application for transverse arrest.

COMPLICATIONS OF LABOR

Prolonged labor cases	
First stage (average)	18 or 9 per cent
Second stage (average)	36 hours 41 minutes
Third stage (average)	1 hour 36 minutes
Delivery	9 minutes
Spontaneous or outlet forceps	196
Midforceps	1
Midforcep rotations	
Occiput posterior positions	3
Transverse arrest	1
Cesarean section for disproportion	3 or 2 percent incidence
Routine L.M.L. episiotomies in all cases.	1 or 0.05 per cent

One case of infected episiotomy
All were cephalic presentations.

DISCUSSION

Although there are not sufficient cases in each group to provide accurate statistical data, a summary of all the cases provides us with definite information relative to labor in the adolescent primigravida. The length of labor in all cases was somewhat shorter than what we consider normal for primipara. Spiller in studying 1400 consecutive primiparas delivered by the vaginal route agrees with DeLee, Nathanson Dauhman Miller and others that the younger the mother the shorter the labor. Our study confirms this belief. The incidence of prolonged labor in this group was 9 per cent which is higher than our incidence of 2.5 per cent for all cases. All delivered spontaneously however and without fetal mortality. Uterine inertia was not encountered and in no instance was it found necessary to employ drugs to stimulate uterine contraction. If allowance were made for ineffectual pains early in labor this incidence would be lowered considerably.

Labor was terminated spontaneously in elective outlet forceps in 196 cases or 98 per cent. Forceps interference was necessary in but 4 instances and 3 of these were for purposes of rotation. This incidence of 2 per cent is within our average incidence and lower than other reports for a similar series. The 1 case in which abdominal delivery was necessary makes the incidence of cesarean section 0.5 per cent. This figure is below our incidence of 2 per cent for all cases. In the entire group few pelvic abnormalities were present and no difficulty was encountered because of lack of development of the individual. Posner and Pulver in studying 100 girls between the ages of 12 and 15 at the Harlem Hospital found

deformed pelves in 17.25 per cent and their operative incidence of 12.8 per cent. Our incidence was but 2 per cent which compares with an incidence of 1.4 per cent reported by Bromberg and Brzezinski in their study of 136 primiparas of 14 to 16 years of age. Our percentage of morbid cases were 6 per cent in contrast to Posner and Pulver's incidence of 22.6 per cent. Our total number of morbid cases consisted of 13 cases: 1 case of infected episiotomy, 3 of upper respiratory infection, 1 of temperature cause unknown, 4 of endometritis, 2 of mastitis, 1 of pneumonia, and 1 of cystitis. We therefore cannot agree with their statement that This is a disquieting factor and shows less fitness for pregnancy in the young group.

The antepartum complications totaled 15 or 7 per cent and postpartum complications 9 or 4 per cent. These figures are within our average for the entire obstetric service. Complications of labor consisted of 8 cases of pre-eclampsia, 2 of prolapsed cord, 2 of abruptio placenta, 1 of placenta previa, 1 of postpartum hemorrhage, 1 of postpartum eclampsia (convulsions), 1 of eclampsia, 1 of cephalopelvic disproportion, a total of 24 cases or 12 per cent.

The uncorrected infant mortality was 4.5 per cent of these 2 or 1 per cent were neonatal deaths. The 1 infant expired 12 hours after delivery complicated by a prolapsed cord. The second succumbed on the 8th postpartum day of a congenital heart defect. The 7 stillbirths an incidence of 3.5 per cent were

RESULTS OF TREATMENT OF EPIDERMOID CARCINOMA OF THE ANUS AND RECTUM

RICHARD H SWEET MD., F.A.C.S Boston Massachusetts

STATISTICAL studies of cases of carcinoma of the rectum have not always given separate consideration to the group with epidermoid carcinoma of the anal canal. It is obvious to anyone who has had experience with these cases that the clinical course and response to treatment of the epidermoid carcinoma group differ in many respects from those of the adenocarcinoma cases. Although these differences have been generally recognized there has not always been a uniform opinion about what they entail. With this fact in mind a study of epidermoid carcinoma of the rectum arising in the anal canal has been made from the case records of the Palmer Memorial and Massachusetts General Hospitals.

Epidermoid carcinoma of the anus is a relatively rare type of rectal carcinoma (1). This fact is borne out by the observation that of 802 consecutive cases of carcinoma of the rectum seen at the Palmer Memorial Hospital only 38 (4.7 per cent) were of the epidermoid variety.

It is well known that in general carcinoma of the rectum occurs in the ratio of approximately 3 men to 1 woman. Of the 77 patients who comprise this group of cases of epidermoid carcinoma, there were only 24 men as compared with 53 women. There is no satisfactory explanation for the fact that this type of tumor is apparently so much more common among women than among men.

CHARACTERISTICS OF THE TUMOR

When it comes to a consideration of the type of treatment to be used, and especially as an aid to the understanding of the course of the disease and the end results of treatment, a knowledge of the gross condition and histological characteristics of the growth is of value.

From the Surgical Services of the Palmer Memorial and Massachusetts General Hospitals, Boston.

Size (Table I) Information concerning the size of the tumor is available in 65 of the cases. In 28 cases the growth was classified as small. In this group were put all those which were confined to the anus itself without evidence of invasion of adjacent tissues and those which were not large enough to encircle the lumen or to extend much into the rectum above. In 37 cases the growth was called large. This group included all annular tumors all those which had invaded the surrounding tissues (perineal fat skin of the buttock or perineum and vagina) or those which had extended into the upper rectum.

Invasiveness In 58 cases the presence or absence of invasion of adjacent tissues (vagina or perineal fat) is known. In all there were 36 cases in which the growth had invaded the vagina or perineal tissues.

These observations make it apparent that only about 39.4 per cent of the cases could be considered favorable insofar as the local extent of the disease is concerned (Table I).

Histological grading In all but 6 cases these tumors were studied from the standpoint of the degree of malignancy based upon the appearance of the tissue under the microscope. Only 7 were called grade 1. In 26 cases the tumor was classified as grade 2 and in 38 cases it was considered to be grade 3.

Groin involvement There were definite metastases to the lymph nodes of one or both groins of 18 patients at the time of the first examination. In 33 the groins were apparently not involved. In the remainder either the groins were not described or the examiner was uncertain about his observations (Table II).

METHODS OF TREATMENT

Of the 77 patients who were observed, 5 were not treated because of (1) the extremely advanced stage of the disease (2) the excessive age of the patient or (3) the refusal of the patient to accept the treatment which was ad-

Chart Types of treatment used in 77 cases of epidermoid carcinoma of the anus and rectum.

vised Of the remaining 72 patients 53 were operated upon and 19 were treated by irradiation (Chart 1)

Surgical cases Of those who were operated upon, 3 with far advanced disease were given a colostomy because of intolerable obstruction 2 had a small localized growth removed by local excision, and 48 patients were given the benefit of radical extirpation of the disease by either the combined abdominoperineal or the colostomy and posterior excision methods.

It is important to observe at this point that in only 13 of the cases in which radical surgery was employed was the growth a small one confined to the anus. In 33 the growth was large and in 23 of these it had already invaded the vagina or perirectal fat (Table III) In other words, in the majority of the cases in which surgery was employed the growth had progressed well beyond the early stages of development. This fact should be kept in mind when comparing the results with those obtained by the use of radium.

The histological grading of the tumors in these 48 cases was grade 1—2 cases grade 2—17 grade 3—28 undetermined—1 case. From these figures it is apparent that the majority were grade 2 or grade 3 and that more than half were grade 3

Combined abdominoperineal excision of the rectum was used in 28 cases. In 24 the opera-

tion was performed in one stage and in 4 it was considered to be necessary to use the two stage technique (Jones method) In the remaining 20 cases a colostomy and posterior excision of the rectum was performed in 5 in one stage and in 15 in two stages. It was possible to use the colostomy and posterior excision in such a relatively large number of cases because of the fact that the growth was low in all. It was chosen frequently because of the fact that the abdominal stage of this operation is much simpler and less upsetting to the patient than that of the combined abdominoperineal excision. This made it possible to operate successfully upon a few of the aged or otherwise relatively poor risk patients. The combined abdominoperineal method was chosen in the better risk cases or because the wide extension of the tumor made it seem that the posterior approach would be inadequate.

Irradiation treatment cases Irradiation by means of roentgen rays radium alone, or both combined was used in 19 cases. Of these 7 patients were treated by deep roentgen ray only. The remaining 12 patients were given radium. In 3 of the latter supplementary roentgen ray treatment was used. The method of treatment varied from case to case, but in the majority of the radium treated cases interstitial irradiation with platinum needles or with gold radon seeds was used. The roentgen ray treatment was usually used only with palliation as an object and was usually not given in doses of larger than 1500 to 2500 roentgen units. Two patients only were treated heavily with doses of 5400 roentgen units and 7500 roentgen units respectively. In all 3 cases in which both forms of irradiation were used, the treatment was begun with radium and x ray was used to treat recurrent disease or metastases to the groins.

Choice of treatment The choice between operative and irradiation treatment was made on the basis of the merits of each case. In gen-

eral radical excision was used in any case in which the patient was a reasonable risk for surgery and also in all those with a growth too large or too inaccessible for radium unless it was inoperable when roentgen ray treatment was given. In a few cases however the decision in favor of the use of radium was undoubtedly made because of the clinician's preference for this method in a low fairly accessible epidermoid carcinoma of the anal canal. In the last analysis, the judgment and experience of the individual surgeon in charge were what determined the decision in each case.

RESULTS OF TREATMENT

Chart 2 shows the results of treatment in this group. Of the 77 cases of epidermoid carcinoma of the anal canal and rectum which constitute the basis of this study the end result is known in 75 cases. Taken as a whole, the results are discouraging especially when compared with those obtained in the adenocarcinoma group. In a very carefully followed series of cases of carcinoma of the rectum, in Jones reported every patient seen by him, Dr D F he had seen to be alive and apparently well at the end of 5 years. In the group of epidermoid carcinomas reported here only 13 patients sent a possible 5 year cure rate of approximately 17.3 per cent of the entire group. Whether or not this relatively poor result is related in any way to the fact that in the epidermoid group an appreciable number of patients were treated by irradiation methods instead of by radical surgery is not certain. But this conclusion is in part substantiated by this report. It is probable that if a larger proportion of pa-

Chart 2. End-results in 77 cases of epidermoid carcinoma of the anus and rectum.

tients had been operated upon a higher percentage of cures would have been obtained.

Surgical treatment. The 3 patients who were treated by colostomy alone died of their disease but 1 survived almost 2 years.

Both of the patients who were treated by local excision of a small lesion died of local recurrence and distant metastases one after 2 years and the other 3 years after operation.

In Dr Jones' report based upon all his cases including epidermoid and adenocarcinoma types radical operation resulted in 55 per cent of 5 year cures (2). In the present series of epidermoid carcinoma of the anus and rectum of the 48 patients operated upon radically (including both abdominoperineal and colostomy and posterior excision techniques) 12 patients lived 5 years or more without disease. If we exclude 3 patients whose operations were performed less than 5 years ago and 2 who are untraced, a 5 per cent cure rate of the operative cases of 28.8 per cent is observed. This should be compared with the 17.3 per cent for the group as a whole. This result might be improved if the abdominoperineal excision were used in all of the cases instead of the colostomy and posterior excision which never results in the removal of as much of the area of lymphatic spread as the former procedure and which in Dr Jones experience with carcinoma of the rectum as a whole resulted in only 37.7 per cent of 5 year cures as compared with 55 per cent in the combined abdominoperineal excision group.

Chart 3 summarizes the results of radical operative excision in the 46 cases in which the end result is known. Twelve are classified as cured. The survival period in this group varies from 6 to 16 years. In 6 of these cases the growth was large and locally invasive. In the remaining 6 cases the tumor was small, but in 2 of these there was definite evidence of invasion of adjacent tissues. In 9 of the 12 cases

Chart 3. Results of radical surgery in 48 cases of epidermoid carcinoma of the anus and rectum.

the tumor was classified as grade 3 malignancy histologically. Eight were operated upon by the abdominoperineal method (one stage) and 4 by the colostomy and posterior excision technique (two stage). It is interesting that all those patients who were operated upon by the colostomy and posterior excision technique survived an unusually long period of time (8, 14, 15 and 16 years respectively).

Three patients are alive and apparently well less than 5 years after operation. These are not yet classified as cured.

The remaining 31 patients are dead. Among this group there were 5 operative deaths. Two of these were caused by acute small intestinal obstruction. Both occurred before the invention of the Miller Abbott tube. In each case an enterostomy performed for the relief of the obstruction was unsuccessful. Today with the prompt use of a Miller Abbott tube these deaths might be prevented. One patient died of pyelonephritis, another of pulmonary edema, and the fifth patient succumbed to postoperative pneumonia.

Of the remaining 23 deaths, all of which occurred in less than 5 years following radical surgical removal, there were 14 patients in whom there was a definite local recurrence of the growth, but there were 9 in whom death occurred from metastases without any sign of a local recurrence of the disease. In other words, as a result of surgery there was good local palliation; that is freedom from recurrence in 23

Chart 4. Results of irradiation treatment in epidermoid carcinoma of the anus and rectum.

cases. Twelve of these were cured and 9 died of distant metastases without local recurrence of the disease. This fact should be kept in mind when comparing the results of surgery with those of irradiation treatment.

The location of distant metastases in the 23 patients who died of recurrent or metastatic disease following radical extirpation of the growth is summarized in Table IV. As one would expect, there was a high incidence of metastases to the groins in this group of cases because of the lymphatic communications which exist between the anus and the inguinal nodes (16 of 23 cases).

Irradiation treatment. Some form of irradiation treatment was used in 19 cases (Chart 4). It would be interesting and valuable to be able to say just why this method was chosen in each of these cases, but from the records this cannot always be done with certainty. An attempt was made to obtain this information from the surgeons in charge, but after the passage of several years it is often difficult to recall just what the reasoning was. Obviously some of the cases had reached the stage of local inoperability and the choice in favor of irradiation was made merely in the hope of producing some degree of palliation. This was true of the majority of the x-ray treated group, 3 of whom already had groin metastases when they were first seen. In many cases it was because the surgeon believed that as a result of either advanced age or poor general condition the patient would not survive a radical operation. Some of these patients if seen today would undoubtedly be operated upon because of the improvements in anesthesia and general preoperative and postoperative care which have

TABLE IV.—DISTRIBUTION OF METASTASES IN 23 CASES IN WHICH THE LOCATION IS KNOWN

Mesenteric nodes	5
Liver	
Spleen	
Lungs	

increased the operability of all types of rectal or colon carcinoma. Some of these patients however were treated with radium in the belief which seems to be held by certain surgeons, that these tumors like epitheliomas of the skin, respond favorably to the effects of irradiation. The truth of this belief remains to be proved by those who subscribe to it. A study of this group of cases tends to lead one to believe that it is erroneous. Chart 4 summarizes the results.

Of the 7 patients who were given x ray treatment alone 3 were inoperable because of metastases to the groins. In each of these cases the growth was a large one but the remaining 4 might have been operated upon with better prospect of palliation if not of cure. All 7 died. None lived more than a year. Two showed a slight temporary regression in the size of the tumor. In none was there any significant relief from pain and tenesmus. As a method of palliation, therefore in these 7 cases x ray treatment was a failure. Those treated with the 400 000 kilovolt apparatus appeared to be no better off than those treated with the 200 000 kilovolt machine.

The details of the treatment and the dosages used varied from case to case but consisted in every instance in the use of platinum needles or gold seeds implanted into the tumor or around its periphery. Of the 12 patients treated, platinum needles were used in 7 gold seeds in 5. In 2 of the patients in whom platinum needles were used seeds were implanted as well. The results on the whole were disappointing. In many of the cases the growth was not large. In 7 of the cases the growth was small and confined at first to the anus itself. In only 3 was it obviously large and in only 1 of these was it invading adjacent structures. In 2 there was no record. The histological grade of these tumors was grade 1—1 case grade 2—6 cases grade 3—4 cases no grading—1 case.

If these tumors as some believe may be expected to respond favorably to irradiation treatment the fact that so many of this group were small and not yet invading the surrounding structures should have assisted in obtaining good results. But on the contrary the results were poor. There was only 1 cure. This

patient is alive and well at the end of 11 years after interstitial radiation with platinum needles. Her growth was a small one. The lesion healed slowly, however, and there was a severe local reaction with much pain and tenesmus lasting several months.

In 6 patients in this group there was reasonably good palliation. In these 6 patients there was a temporary complete disappearance of the growth for from 2 months to 4 years. Two of these patients may have been cured of their anal carcinoma, but the end result could not be known because both died of some other disease. One died 4 years later of a carcinoma of the breast. The other died after 2 years of gangrene of the foot. In both cases the growth was small and both were treated with gold seeds alone.

In 5 cases there was no regression. In all of these the pain and tenesmus induced by the radium treatment in addition to the discomfort already present made them most uncomfortable.

Of the 11 patients who received radium treatment and were not cured, all are now dead (2 of intercurrent disease as stated). The survival period in this group varied from 3 months to 5 years. These results are most disappointing.

COMPARISON BETWEEN THE RESULTS OF THE TWO PRINCIPAL METHODS OF TREATMENT CARRIED OUT

Although there were relatively more small and locally favorable tumors in the irradiation treated group than in the surgical group the results both as to cure and good palliation were notably superior in the latter. Radical surgery produced cures in 12 of 48 cases (25 per cent) whereas in the irradiated group only 1 in 19 was cured (5.2 per cent). In the majority of the surgically cured patients the growth was large and invasive. In the 1 radium cure case the tumor was small and not invasive. Leaving aside the question of cure, the degree and duration of relief from local symptoms is important. Here again the results of radical surgery are better. In 21 surgically treated cases there was no local recurrence. Thus 41.6 per cent of the patients operated upon experienced complete relief from the local discomfort.

fort produced by the growth. In only 6 of the irradiation treated cases was there even temporary disappearance of the growth and relief from pain. In 1 of these there was a cure. Two died of other causes but in 3 there was a recurrence of the disease. There was therefore if we exclude the recurrent cases a degree of palliation in the irradiation treated cases comparable to that obtained by surgery in only 15.8 per cent of the group.

One must conclude therefore, that irradiation treatment is not as satisfactory as radical surgical excision either as a method of cure or as an attempt to secure relief from the distressing local symptoms of epidermoid carcinoma of the anus and rectum.

THE treatment of jaw fractures and associated facial injuries, together with severe burns and miscellaneous problems of plastic surgery arising in the Canadian Army Overseas in the late war, was centralized in the plastic surgery division of Basingstoke Neurological and Plastic Surgery Hospital, Royal Canadian Army Medical Corps. This plastic surgery service was organized and commanded originally by Lieutenant Colonel Stuart D Gordon. The association of neurosurgery and plastic surgery in one hospital was very valuable because craniocerebral injuries so often were associated with wounds of the face and jaws, and in numerous cases the plastic surgeon was able to provide full thickness coverage in loss of skull and overlying scalp after debridement by the neurosurgeon.¹

In all, around 3,000 patients were treated by the plastic surgery service or between 5 and 6 per cent of Canadian casualties.² Of this number as might be expected, by far the majority followed the evacuation of wounded from Italy in the late months of 1943 up to D' Day and with marked increase after that the work being maintained at a high volume until 'VE' Day.

Our experience was varied. In the early period it was concerned with training accidents with wounds essentially of civilian character and casualties the result of enemy bombing of civilians. To these were added definitive surgery in late cases of patients arriving from Italy these patients were treated as long as possible before repatriation. Following D' Day until hospitals were established on the Continent there was a period when patients came to us relatively untreated though with surprisingly little delay. Subsequently, most of the patients with facial in-

juries received their primary treatment at the hands of one or other of two British maxillo-facial surgical units under the command respectively, of Major Hynes and Major Fitzgibbon, to whose excellent work we are indebted.

As mentioned previously our experience covered all phases in the treatment of the jaw wound, whether they resulted from simple trauma or from missile injury. Statistics quoted represent individual patients, not individual fractures of either mandible or maxilla. Of the whole series detailed analysis has been made of all those patients admitted between January 1, 1944 and July 15, 1945 with the exception of those who died or those who required bone grafts. The figures shown in the tables suffice to exemplify typical features of treatment and complications.

TABLE I.—PATIENTS WITH JAW WOUNDS
JANUARY 1944 TO JULY 1945

Mandibular fractures—All types	No. cases
Maxillary fractures	369
Mandibular fractures—gunshot wounds	236
Mandibular fractures—simple trauma	256
	113

MANDIBULAR FRACTURES

Simple trauma For purposes of treatment the jaw is arbitrarily considered in four parts: condyle or ascending ramus including the neck, the angle coronoid compound from base of condyle to the last molar tooth, the ramus or horizontal ramus and the symphysis.

If reduction is accurate and fixation adequate these fractures heal well and are united in 6 weeks. Union is estimated by clinical criteria—no spring or pain at the fracture site on manipulation or mastication long before it can be confirmed radiologically. If infection occurs union is delayed for an average of 12 weeks. It is in this type of fracture that nonunion most often occurs. Fractures of the

¹There were 18 cases of this type.
²Based on report of Canadian casualties dated December 28, 1945.

ramus and symphysis are always compound into the mouth, and reduction and fixation are urgent if infection is to be avoided. In our analysis, a delay of 4 days between fracture and reduction, gave marked increase in infection. Surprisingly a firm tooth in the fracture line appeared to have little influence on the incidence of infection, in fact the evidence pointed the opposite way possibly because an alveolar gap may have been created in an effort to remove the tooth. Certainly if it represented a single tooth in the posterior fragment, its utility in maintaining reduction was such that it was retained if at all possible. It may be that in older patients in civilian practice showing a less ideal mouth hygiene than existed among our soldiers a tooth in the fracture line would be less well tolerated with less danger of carrying away alveolus in its removal.¹

TABLE II.—METHODS OF FIXATION OF MANDIBULAR FRACTURES

	No. cases
Interdental and intermaxillary wiring	14
Cast cap splints	83
Interosseous wiring	40
External pin fixation	7
Circumferential wiring	
External angle wire to plaster of Paris board cap or to bar on cast cap splint	4

Fixation. In methods of fixation our practice differed widely from that of our British confreres who treated the majority of patients with cast cap splints. Perhaps their predilection for splints is due to the loss of teeth and irregular spacing of remaining teeth so frequently found in their patients, even in the age group encountered in the Army. We used cast cap splints in the same relatively edentulous type of patient, but in our soldiers the loss of teeth almost always coincided with their injury. One cannot speak too highly of the fine state of mouth hygiene preserved by the Canadian Dental Corps in the units of our Army.

We of the plastic surgery service were especially fortunate in the caliber of the officers attached to us by the Canadian Dental Corps, in the early days of the unit Major (later Lt.

Col) G Franklin and later Lieutenant Colonel V Jekill Major A. T. Roger M. B. E. and Major G MacDonald, M. B. E. The latter two were most intimately concerned with the work in the operating room and the wards. Each patient was seen by surgeon and dental officer in consultation and the method of treatment determined. In many cases, this was carried out by the dental officer until fixation was removed and the patient was again seen in consultation for final appraisal before discharge. In all cases the dental officers assisted in the routine postoperative care in the wards. Patients with complications from the beginning or in whom complications developed were operated on by the surgeon with the assistance of dentist to provide fixation. In this way our usual aggregation of 50 or 60 patients with fractured jaws was under the closest observation with a minimum of overlapping. Fracture of the mandible of civilian type due to simple trauma is usually of ramus (including symphysis) or angle coronoid and the opposite condyle. A condyle fracture alone, even in the presence of luxation of the head is treated by fixation in good occlusion for 2 weeks to prevent shortening on the side of fracture. Early mobilization is necessary to avoid trismus which is prone to occur in such case after prolonged fixation of the jaws.

Angle coronoid fracture is not likely to be compound but the posterior fragment is prone to upward and inward displacement with consequent malocclusion. Reduction may be retained by a bite block and intermaxillary fixation but is usually disappointing both in reduction and fixation. Open reduction and interosseous wiring is most satisfactory combined with interdental and intermaxillary (I.D. and I.M.) wires. Pins may be used in this type of fracture if preferred. Angle coronoid fractures unite freely but upward displacement of the posterior fragment must be guarded against, for if present it seriously interferes with fitting of a denture and sometimes with occlusion and mastication.

Ramus fractures are always compound into the mouth. Treatment is urgent on this account, though not an emergency unless through bilateral ramus fracture the patient is unable to swallow. In such case it is im-

¹From an analysis of 33 cases of fracture due to simple trauma in this series 1940 to May 1944.

portant that he be treated face downward until the jaw is fixed to prevent him drowning by aspiration of blood and saliva. As previously pointed out a tooth in the fracture line should be retained if it is alveolar or is one of two in the posterior fragment and is firm. If the ramus is edentulous or the posterior fragment is edentulous the fracture must be treated in the same way as an angle fracture. In most cases of ramus fracture, eyelet wires and intermaxillary wires or some suitable combination of arch wire, or arch bar and intermaxillary wires give satisfactory reduction and fixation. The fracture is tested for union in 5 to 6 weeks and should not be considered a case of nonunion for at least 3 months unless gross infection has occurred.

Nonunion of ramus and symphysis fractures may be due to failure of reduction and fixation but occasionally it is difficult to explain. The chief factor in nonunion is infection. Nonunion is to be expected in case of bone loss involving the whole depth of the mandible. It is not important in the condyle except in consideration of adjacent soft tissue damage leading to trismus. Movement must be started early in from 2 to 3 weeks to avoid nonunion. Due to whatever cause fracture due to gunshot wounds with loss of bone though of course the reconstruction is far less formidable.

TABLE III.—GUNSHOT WOUNDS OF MANDIBLE

	No cases
Gunshot wounds with ramus fracture	154
Gunshot wounds with condyle fracture	37
Gunshot wounds with angle coronoid fracture	65
Mandibular fracture with bone loss	73
Mandibular fracture with soft tissue loss	30

Gunshot wounds of mandible Bone loss is a term used in this group to indicate loss of a section or sections the full depth of the jaw and thus to distinguish the case as a problem in treatment different from the fracture due to simple trauma. Where a portion of the alveolus is knocked off in association with a fracture through the body of the bone simple débridement of bone and soft tissue wound with closure of the latter to cover the bone and with the type of fixation used for a fracture due to simple trauma is the treatment. A free

graft to deepen the sulcus is commonly necessary before a dental prosthesis can be fitted. Similarly, if a piece of bone is fractured from the lower border of the ramus it usually retains enough soft tissue attachment to provide a blood supply and may be ignored. The troublesome case is that in which there is gross comminution of bone. A thorough débridement must be done that is scrupulous removal of all bone fragments with doubtful blood supply of tooth fragments and devitalized soft tissue and complete closure of the soft tissue wound. If there is not enough soft tissue available inside the mouth for restoration mucosa must be sewed to skin edge over the bone ends. It is quite easy to locate and remove bone fragments detached from soft tissue in the recent wound, but if they are allowed to remain the wound will suppurate and in the presence of the resultant edema granulation and scar tissue it may be impossible to locate them.

Fixation of the fracture with bone loss is best done with sectional cast cap splints if teeth are available. Impressions are made for these at the time of débridement and they are cemented in place 1 or 2 days later an anesthetic being unnecessary. This splint retains the normal relative position of the fragments and is the final fixation until union occurs after bone graft. In case there are not enough teeth available the alternative fixation is by external pins.

Fractures with any appreciable amount of bone loss require a bone graft for union if deformity is to be avoided. In case of nonunion of a fracture due to simple trauma or if bone loss is less than $\frac{1}{2}$ inch the graft may be of medullary chips. The ends of the fracture fragments must be freshened and intervening scar tissue removed. Enough of the outer cortex adjacent to the fracture must be removed to get free contact between the chips and the host. The wound is not drained and a pressure bandage is applied for 48 hours to prevent any possibility of hematoma.

Bone grafts in mandibular fractures In larger defects, a combination of cortical bone and medullary chips is used. The graft is obtained from either iliac crest which is exposed and split longitudinally for a little more than

TABLE IV — BONE GRAFTS IN MANDIBULAR FRACTURES

	N cases
Gunshot wound bone defects iliac cortical block and medullary chips	70
Simple trauma cancellous graft	3
Total series 1940-1945	73

the estimated required length of graft. The inner half is removed for a depth of about 3/4 inch by checking with an osteotome, then with a narrow osteotome a considerable yield of medullary fragments may be obtained. If only medullary bone is required the cortical block is driven back into its place. If the cortical block is to be used as graft a moderate amount of medullary bone is left attached to it. The jaw fragments are now exposed and prepared as described previously the cortical block is suitably shaped and wired firmly to the fracture fragment at each end, cortical side out, and small medullary chips are packed around its ends and beneath it.

Penicillin and chemotherapy have markedly cut down the morbidity in these cases. Bone grafting can usually be done 3 to 4 weeks after the primary débridement and closure of soft tissues instead of in as many months. Practically all bone grafts were done in England as a routine measure in spite of pressure of other work, in view of the fact that the jaws had to be fixed in occlusion until union was procured and of possible delays in repatriation and in resumption of active treatment at home. In this way it was possible to avoid much discomfort and inconvenience to the patient. Actually firm clinical union was the rule in 6 weeks from operation and the majority of these patients were observed to this point. It is probably unwise to send a patient on a stormy Atlantic crossing with his jaws wired together.

Complications of bone graft were few. There was no case of osteomyelitis of ilium. An abscess occurred in the soft tissues outside the jaw in 5 cases, but in each case yielded to simple drainage and chemotherapy without loss of graft. We saw only 1 case of nonunion after bone grafting and 1 other case in a repatriated patient is known to us. A complete survey of these repatriated patients has been impossible to date.

TABLE V — FRACTURES OF THE MAXILLA

*Series of cases January 1944 to July 1945.
 †Union secured with bone graft.

Trismus is rarely troublesome in mandibular fractures but is a feature in fractures and gunshot wounds of the condyle and coronoid. It is most common in what appear to be relatively simple through and through wounds of the middle of the face from bullets. Probably the mechanism is the same in both cases and is due to side to side adhesion of muscle and fascial planes. It can be avoided by early mobilization but, once established is very difficult to overcome. Forced mobilization under anesthesia only results in recurrence in aggravated form. Dental exercisers are disappointing the best results are from graduated bite blocks worn 24 hours daily until the opening is enough to admit solid food.

MAXILLARY FRACTURES

Fractures due to simple trauma range from fracture of a portion of the alveolus to complete separation of the maxilla from the skull the mid third fracture or floating maxilla so often seen in motor cycle accidents and frequently complicated by being comminuted through palate and alveolus. The alveolar fracture is easily treated by wiring the teeth in occlusion. The more severe type requires repair of the mucoperiosteum of the palate, if this bone is broken and in addition to inter dental and intermaxillary wires, a plaster of Paris chin cradle and head cap connected by two lateral rods adjustable through universal joints. The problem of insufficient remaining teeth is met by wiring a Gunning splint to the alveolus. The simple alveolar fracture unites in 3 weeks the more severe fracture requires fixation for 4 to 6 weeks. Infection and nonunion are rare.

When a missile traverses through the cheek and maxillary sinus and lodges, perhaps, in the pterygoid fossa or the neck on the opposite side, it is usually quite easy to remove it by following the track or by making a counter incision in the neck. We felt that removal was

wise for fear of infection from the sinus and danger of secondary hemorrhage from the large vessels of the neck. Many bone fragments were driven into the maxillary sinus and débridement and closure of the wound were combined with a Caldwell Luc antrostomy when the antrum could be cleaned out and indirect drainage of the wound track provided by making a large window into the nose.

In cases in which the missile traversed the face and which we termed a "blow-out" because of the wide destruction of soft tissue of the cheek at the site of exit, careful débridement of the wound was done, free drainage into the nose provided from both maxillary sinuses though this was usually present from the nature of the wound and every effort made to close the cheek wound by undermining or by rotating a cheek flap. No attention was paid to lining in such case in the hope that it would regenerate from the antral mucosa and this appeared to be the case. Careful débridement of bone and devitalized soft tissue and avoidance of dead space are essential. In some cases, especially if a good deal of the zygoma was lost, dead space was obliterated by rotating a flap of temporal muscle. Penicillin and chemotherapy undoubtedly are of great assistance to the natural defensive forces against infection but are of no avail unless débridement is scrupulous and fluid collection is avoided. Hemorrhage often severe in this location is usually controllable with fibrin foam but in a few cases it was necessary to ligate the external carotid artery.

TABLE VI.—COMPLICATIONS OF FACIAL WOUNDS

Secondary hemorrhage	6
Osteomyelitis	15
Tracheal obstruction (tracheotomy)	34
Gastrostomy required	1
Eye enucleation or eversion	66
Eye trauma	80

COMPLICATIONS IN FACIAL WOUNDS

The relative rarity of secondary hemorrhage is remarkable. Intramuscular penicillin was started with the first treatment of our casualties and was continued in regular dosage throughout evacuation to base hospital. In no case did we find spreading infection on

arrival and to penicillin treatment and to careful débridement must be attributed the rarity of secondary hemorrhage. Tracheotomy was wisely done by the maxillofacial surgical unit in all cases in which there was any doubt of airway obstruction during evacuation. It was only occasionally required otherwise.

Operation in these cases is not an emergency measure unless because of hemorrhage respiratory obstruction or inability to swallow. In fact it should be deferred for a few hours for on arrival the patient is tired, cold and hungry. Clinical check is followed by immediate x-ray examination in those cases in which high priority for operation is indicated. Removal of dirty, blood-caked clothing, a hot bath, hot nourishing fluids, and a sedative lead to a few hours of sleep and relief of "battle fatigue" and make the patient a much better operative risk. In case clinical examination of the chest, checked by radiological examination if necessary shows evidence of aspirated fluids these are removed through a bronchoscope before operation.

Credit to Major R. A. Gordon our anesthesiologist and his staff cannot be too high. Pre-operative resuscitation was under his supervision, and he was continually alert for post-operative pulmonary complications. He frequently had occasion to aspirate large amounts of blood and mucus saliva from the lungs before operation and in this way and in prompt bronchoscopic cure of collapse of the lung when it occurred after operation chest complications were avoided. Blood transfusion was done freely during operation for it was found more economical to keep the patient out of shock than to resuscitate him when shock had already taken place. These operations were frequently prolonged and often attended with a good deal of unavoidable hemorrhage.

There was only 1 death in our cases of jaw and facial wounds.

Private L. S. G41607. Shell wound enemy action. Wounds consisted of compound fracture of right humerus, both jaws, and chest received July 28, 1944. Treatment No. 5 maxillofacial surgical unit débridement of arm and plaster cast débridement of jaw and face and intermaxillary fixation were carried out. He was admitted to Basingsstoke Neurological and Plastic Surgery Hospital August 5, 1944. Patient was

very ill but as x ray examination showed multiple bone and tooth fragments in the fractures of both jaws, and the previously sutured facial wounds were partially separated exposing bone operation was carried out. Two bottles of blood were given during operation. Operation consisted of debridement of tooth and bone fragments from both jaws, interosseous wire to lower jaw debridement of soft tissues, and repair to cover exposed bone. His condition was not good enough to permit taking care of the arm fracture. Penicillin was given in 100,000 units daily sulfathiazole grams one every 4 hours for 5 doses intravenous glucose saline 5 per cent 3,000 cubic centimeters daily. Condition was improved until August 9 when he became confused mentally and lethargic. He vomited occasionally. Urinalysis was + plus albumen red blood cells and white blood cells, nonprotein nitrogen 436. Steady deterioration and uremia occurred resulting in death on August 16 1944. Nonprotein nitrogen 450.

This man had had 12 transfusions before he was admitted to our care. Necropsy showed his kidney tubules plugged with blood. It was a remarkable feat that our soldiers were supplied with blood so freely. Even at our level, only Type O blood was supplied. Transfusion accidents were very rare, and in our experience this was the only case in which there was a fatality.

FEEDING ROUTINE FOR JAW CASES

Types of diets. (a) Jaw fluids. (b) Jaw No. 1 (c) Jaw No. 2

Methods of feeding. Patients with gunshot wounds of mouth are fed a completely fluid diet of 1800 calories, plus a special tube feeding of 800 calories. Patients should be fed in a prone position in order to prevent regurgitation of the liquids. The patients are fed with a rubber tube on the end of a large glass syringe or a bulb syringe.

Jaw fluid diet consists of 1800 calories. If patient is able to purse the lips and does not have a paralyzed tongue, he may drink the fluids from a feeder. Otherwise patient has rubber tube inserted between the molars and the cheek and the liquid is poured slowly through the tube from a feeder. If opening is inadequate, fluids may be forced gently between the teeth by a bulb syringe.

Jaw 1 diet consists of 2600 calories. All the food is purged and all beverages strained. This diet is fed to the patient all the time the splints are on. Patient carries the purged food to the lower lip by spoon, and then sucking and pushing (by the finger) gets the food into the mouth.

Jaw 2 consists of 2600 calories. Only the meat remains purged, no raw salads are given. This diet is given when the patient has had the splints removed.

To all diets is added ascorbic acid, 100 milligrams, and vitamin D oil, 1/4 ounce daily. The patient must be encouraged to eat the jaw 1 diet at the earliest possible moment. This jaw 1 diet

is better balanced has more calories, and gives greater variety than the fluid diet. The jaw fluid diet is used only for 24 to 48 hours except in the case of patients with gunshot wounds and special patients who may need fluid diet for a longer time because of particular injury.

It is always important that the food be presented to the patients in as attractive a manner as possible and that a wide variety of tastes to attract his palate be used.

SUMMARY

An analysis of fractures of lower and upper jaws is submitted. These fractures were of two types, namely civilian type and those due to gunshot wounds. Types of fixation are indicated in their respective frequency of employment.

With careful debridement associated with penicillin and chemotherapy and by carefully planned closure of soft tissue wounds, it was possible to avoid much soft tissue deformity. Similarly in comminuted fracture of the mandible, treatment consisted of careful debridement of all planes of the wound especially aimed at removal of any bone fragment without soft tissue attachment or with doubt full blood supply obliteration of dead space, and complete closure of the overlying soft tissue without drainage. Following this procedure there was rarely any further sign of infection necessitating further debridement. Bone grafting was done within a month after primary closure in those cases in which it was indicated and was practically always successful with minimal complications.

Secondary hemorrhage was rare probably due to adequate surgery and avoidance of infection. Penicillin and chemotherapy are of great value in limiting infection but the greatest factor is still careful surgery.

In civilian type fractures with nonunion or in fractures with a gap of less than 1/2 inch bone graft was of medullary chips alone from the iliac crest. In larger gaps, a block of cortical and medullary bone was wired firmly to both fragments of mandible, supplemented by medullary chips beneath it and around the ends.

Some practical suggestions regarding the care of wounds of this kind and regarding dietary requirements are included.

SURGERY OF THE POSTERIOR INTEROSSEOUS BRANCH OF THE RADIAL NERVE

Analysis of 58 Cases

JOHN H. MAYER, Jr., Captain M.C. Kansas City Missouri and
FRANK H. MAYFIELD Lieutenant Colonel M.C. Cincinnati Ohio

LESIONS of the posterior interosseous branch of the radial nerve have been considered unamenable to surgical repair by many surgeons. Reluctance to attempt repair has been based on the belief first that gaps could not be overcome because of the straight course of the nerve second that widespread arborization prevented end-to-end suture and third that tendon transplantation provides an adequate substitution with a much shorter convalescence. Experience in the Neurosurgical Section at Percy Jones Hospital Center indicates that these objections are not valid.

The primary purpose of this paper is to present the data from 58 patients treated surgically. These data demonstrate that surgical repair may be accomplished satisfactorily in a high percentage of cases and that the results justify the attempt. It is our further purpose to discuss in some detail the diagnosis and surgical treatment employed.

ANATOMY

The radial nerve after giving off motor branches to the extensor carpi longus and brachioradialis divides just distal to the elbow into its two terminal branches the superficial radial nerve and the deep or posterior interosseous branch. The latter nerve then passes deep to the extensor carpi longus and enters the fibers of the supinator muscle. Coursing obliquely around the head of the radius it emerges from the supinator fibers on the posterior aspect of the upper one-third of the forearm. Textbooks of anatomy depict immediate branching of the nerve as it leaves the supinator fibers. In our experience it often arborizes 1 or more inches below the supinator muscle.

Read before Surgical Conference, Sixth Service Command, July 28, 1943, Chicago, Illinois.

The nerve supplies the extensor communis digitorum, extensor carpi ulnaris, extensor pollicis longus and brevis and abductor pollicis longus. No significant sensory component is present in the nerve.

DIAGNOSIS

Paralysis of the muscles which this nerve supplied produces a characteristic deformity of the hand (Fig. 1). Dorsiflexion of the wrist is preserved by the extensor carpi longus. Paralysis of the extensor communis digitorum renders extension of the proximal phalanges of the fingers impossible. Extension of the distal phalanges is preserved, since this movement is performed by the interossei and lumbricales. Paralysis of the extensors of the thumb prevents active extension of all joints of the thumb and paralysis of the long abductor prevents abduction of the thumb in the plane of the palm. The thumb in repose assumes a position of slight flexion being immediately ventral to the index finger. When forceful extension of all digits is attempted, apparent extension of the index finger may be accomplished in a passive manner by strong contraction of the adductor and the opponens pollicis.

SURGICAL TECHNIQUE

Exposure of the deep branch of the radial nerve is secured through an incision (Fig. 2) overlying the fascial plane between the brachioradialis and biceps muscle on the lateral aspect of the distal portion of the upper arm extending lateral to the antecubital fossa and over the posterior aspect of the upper portion of the forearm between the brachioradialis and the extensor carpi radialis. The radial nerve is identified between the brachioradialis and the biceps tendon and dissected downward to the site of injury. Care must be taken to preserve

Fig. 2 Typical deformity on attempted extension of all digits in paralysis of posterior interosseous nerve

the motor branches to the brachioradialis and extensor carpi longus. The nerve is then picked up immediately below the supinator fibers by separating the extensor carpi longus and extensor communis digitorum. The proximal neuroma and distal glioma are resected back to healthy fascicles. Gaps measuring up to 50 centimeters are easily overcome by freeing the nerve up to its parent trunk and flexing the elbow to 90 degrees. Anastomosis is accomplished with sutures of 003 tantalum or No 000000 black silk placed through the epineurium of the divided nerve ends. No stay suture has been employed except in cases in which tension on the suture line was thought to be unduly great. Tantalum foil

Fig. 3 Full recovery of all muscles 10 months after operation

has not been used. The elbow is immobilized in the flexed position by means of circular plaster with the forearm in slight pronation the wrist in cock up and the fingers and thumb free. The plaster is removed in 4 to 5 weeks and immediate physiotherapy is begun without restriction upon the rapidity with which complete extension of the elbow is secured.

RESULTS

Of the 58 patients (Table I) subjected to surgical exploration of the deep branch of the radial nerve neurotomy was done in 39, in 2 cases it was necessary to repair the divided nerve by means of an autogenous graft obtained from the superficial radial nerve; the nerves in 14 cases required neurolysis only. In 3 cases, for reasons which will be described it was impossible to secure repair of the nerve.

For appraisal of results the patients have been divided into two groups: group I, includes cases in which repair was performed prior to May 1945; group II, those cases in which repair has been carried out since that time. Though 2 of our patients have shown earliest signs of recovery during the seventh and eighth months, we have included for final evaluation all cases in which repair was effected 6 months or more prior to this report. Of the 37 cases comprising group I, neurolysis only was performed in 9, end-to-end suture in 24, the use of an autogenous graft to overcome

gap in the nerve in 2 and complete failure to secure repair in 2 cases.

The deep branch of the radial nerve being purely motor lends itself to simple evaluation. We have divided our patients into those who have obtained what we call full recovery (Fig 3), in whom all the muscle groups supplied by the deep branch of the radial nerve function with at least 50 per cent of normal motor power; partial recovery (Fig 4), in whom recovery in some but not all, of the muscle groups supplied by the nerve has taken place, or in whom all muscle groups have recovered but one or more of them in a defective manner (Fig 5).

Evaluating the cases of neurorrhaphy observed longer than 6 months after operation (Table II) in the 26 patients so treated full recovery has been obtained in 19 or 72 per cent of the cases. Partial recovery has been noted in 3 cases and failure of any evidence of muscle return in 4 cases. Two of the patients with partial recovery were operated upon less than 8 months ago and further evidence of recovery in the muscles still paralyzed is anticipated. It should be noted that the 26 cases considered for evaluation of end result includes the 2 patients in whom graft was necessary to secure repair.

DISCUSSION

The data leave little doubt about the feasibility of repairing this nerve in a high percent

age of cases. Attempt to repair the divided nerve met with failure in 3 cases representing 6 per cent of the total group. One of these patients had been struck by fragments of a phosphorous shell and had in addition to the soft tissue damage caused by the metal fragments extensive phosphorous burns of the proximal third of the forearm. The area normally occupied by the deep branch of the radial nerve was replaced by such dense scar tissue that identification of the nerve was impossible. The remaining 2 cases of failure were in patients with extensive soft tissue damage and severe comminuted fractures of the upper end of the radius with generous callus formation. In these cases as in the first, scar tissue and callus replaced the area through which the deep radial nerve coursed.

The 4 patients in whom repair was secured, but in whom recovery has not taken place deserve special consideration. In 1 of these patients E. S. the original injury to the nerve was incurred 3 years prior to surgical exploration and was the result of a surgical accident during operative removal of the head of the radius in civilian life. Because of the long period of time which had elapsed prior to repair of the nerve only 4 months postoperative observation was allowed before tendon transplantation was undertaken for at that time electrical reactions indicated complete denervation. In the second patient, A. M., end to-end anas-

HISTOPATHOLOGY OF THE GASTRIC SEMISQUAMOUS EPITHELIAL LAYER

FREDERIC DURAN JORDA M D (Barcelona) Manchester England

HAVING described previously (1) the semisquamous epithelial layer (Fig 1) which covers the normal gastric and intestinal mucosae we are now going to describe the different histopathological syndromes found by making a study of a fair number of resected specimens of stomach

PATHOLOGY OF THE GASTRIC SEMI SQUAMOUS EPITHELIAL LAYER

The specimens were carefully studied for the presence of all abnormalities principally erosions and afterward we took a photographic record of the fresh specimen, or made a schematic drawing so that after formalin vapor fixation we could select the parts which appeared to be pathological in the fresh specimens. We adopted this procedure because after fixation the mucosa assumes a dark brownish color and small alterations and erosions fade out and are very difficult to find.

Erosions We studied the erosions very carefully as we hoped to gain a better understanding of the problems of ulceration through these small gastric lesions. In the first place we supposed that any erosion indicated a preulcerative process or was actually a very tiny ulcer, and we were extremely careful to avoid the neglect of any details. We selected the whole portion containing the erosion for study and made it into a paraffin block for serial section. As a result of this we have been able to describe the full meaning of erosions that is, the erosions which represent preulcerative processes, and the erosions which represent the postulcerative processes and which will be described later.

Preulcerative erosions Our observations made during the study of the preulcerative lesions disagree completely with the descriptions of the same process as given by different

authors as they have not been able to consider the significance of the semisquamous epithelial layer when making a study of these lesions.

Our investigations of the preulcerative lesions have brought us to the conclusion that they have two typical characteristics. One is the lesion of the semisquamous layer itself and the other is in the mucous membrane.

The lesion in the semisquamous layer itself is represented by an extensive infiltration of round cells and polymorphs which are linked by means of a cellular bridge with the submucosa in a similar way to that which takes place in ulcerative colitis. This bridge contains occasionally small capillaries and the layer may be thick and irregular in appearance (Fig 2).

The lesion in the mucous membrane is characterized by an intense disorganization of these glands and some of them appear to be breaking up their morphological structure and there is an extensive infiltration of polymorphonuclear and round cells. It is still possible however to recognize normal parts of the gastric mucosa (Fig 3).

Ulcer The study of ulcers was made by means of a similar technique to that used for investigation of the erosions, and the whole ulcer was embedded in a paraffin block and made into sections. We carried out our observations on serial sections and these were of great interest principally in the edges of the ulcer at the union between the normal gastric mucosa and the ulcer itself.

As we had expected we found that the semisquamous epithelial layer was missing from the gastric ulcers and by making sections of the whole ulcer, it could be appreciated that the layer disappeared after covering the normal mucous membrane at the edges of the ulcer and was absent from the center of the ulcer (Fig 4). In some ulcers it could be seen how the crater contained some slough

From the Department of Pathology, Ancoats Hospital, Manchester, England.

Fig. 1

Fig. 2

Fig. 3

Fig. 4

tissue, and it was doubtful if this really represented the semisquamous epithelial layer but further observations cleared up this doubt. When the ulcer was stained with thionin it could be seen that the crater was full of microorganisms, some of them included in parts of the tissue itself forming what appeared to be colonies. When stained with mucin stains, the material contained in the crater of the ulcer had none of the characteristics of mucus. Another observation we made was that in some ulcers there was a foreign body included in the crater of the ulcer. Studying the ulcer crater by high magnification it can be seen that the semisquamous tissue disappears at the edge as an independent morphological structure and the crater itself is formed by an accumulation of round cells which are linked together by fibrotic tissue and plasma (Fig. 5).

After these investigations, therefore we can conclude that the crater of the ulcer is without any protection from the semisquamous epithelial layer.

At the edge of the ulcer and covering the mucous membrane can be found capillaries or venous dilatations, some of them being the

largest vessels we have found in the semisquamous epithelial layer of the gastric mucosa (Fig. 6).

The protective function of the semisquamous epithelial layer is fully demonstrated by the study of the process of cicatrization of the ulcer. We have divided the mechanism of healing and mucous membrane reconstruction into 4 parts.

In the first one we can see how the semisquamous epithelial layer begins to grow from the edges and covers the upper part of the ulcer and in some cases a bridge is formed, and under the cover of the new layer the mucous membrane spreads toward the center of the ulcer (Fig. 7).

By the second process the mucous membrane cells using the protection of the bridge formed by semisquamous cells, form islands of mucous cells floating in the space between the protective layer and the new mucous membrane, and these free accumulations of cells will form new glands (Fig. 8).

The third process can be found in the crater of the ulcer itself where occasionally there are islands of mucous membrane cells which ap-

Fig. 12. Postulcerative process. Notice the complete mucous membrane which is found to be unicellular in some cases, and the presence of a strong semisquamous epithelial layer.

Fig. 13. Final healing process of an ulcer. Notice what appears to be an atrophic mucous membrane, and a complete semisquamous epithelial layer.

pear to be protected by semisquamous epithelial cells and under this protection they are able to begin another process of healing by spreading toward the edge of the ulcer (Fig. 9).

The fourth process is more a process of reconstruction than a proper healing mechanism. From the layer of new mucous membrane cells we could see how they project groups of cells like fingers and these projections go toward the making of new glands. But in this case

the whole mucous membrane is fully protected by a new semisquamous epithelial layer (Fig. 10).

It is important to mention here that when studying the cellular morphology of the new healed mucous membrane one is struck by the fact that there are present a large quantity of polymorphonuclear leucocytes, which by following exactly the same mechanism of growing their protoplasm and losing their nuclei

Fig. 4. Pseudoulcer from the pyloric region of a stomach, which shows a gap in the mucous membrane. Notice that the gap is covered by the semisquamous epithelial layer which comes in contact with the Brunner glands.

Fig. 5. A gap in the pyloric region which is occupied by what appears to be venous sinus.

as we have studied in the milk and pus cells (3, 4) settle there and form the new mucous membrane layer. The cells of the new mucous layer have the appearance of cuboid cells with a nonmucous protoplasm very similar to some epithelial cells, which form the wall of breast cysts or the glandular cells making up the structure of the acini in colloid goiter and later on these cuboid cells begin their secreting process and have the aspect of normal mucous membrane cells (Fig. 11).

Postulcerative process. Studying the mechanism of ulcer cicatrization we could recognize the difference between an erosion which precedes a gastric ulcer or an erosion which follows it. It is necessary again to remark that the picture of a postulcerative process has been taken by a number of authors to mean a preulcerative process. The basic difference is that in the postulcerative lesion there is a perfect and what appears to be healthy semisquamous epithelial layer with some cellular

infiltration present but it is not linked with any cellular bridges as we have seen in the preulcerative process and on the other hand the mucous membrane has the appearance of a very atrophic mucosa with a very good mucous cellular layer. Sometimes this is monolayered and without any other glandular structure and the appearance of the mucous membrane cells in cuboid form, as we have previously explained in the description of the formation of the new mucous membrane (Figs. 12, 13).

Pseudoulcer. It is interesting to find when studying different gastric mucosa, how occasionally in different parts of the stomach, but principally in the pyloric region it is possible to observe a gap in the mucous membrane where the whole mucous membrane layer is missing but this part is without any cellular reaction of the submucosa and the gap is covered and protected by what appears to be a healthy semisquamous epithelial layer.

Fig. 8. Section of tissue removed from gastric carcinoma which shows a total disorganization of the gastric glands but what appears to be a well-defined semisquamous epithelial layer.

In some cases the spaces where the mucous membrane is missing are occupied by large blood dilatations similar to small angiomatous conditions (Figs. 14, 15). This is one of the facts which called our attention when we began to study the semisquamous epithelial layer. The absence of the mucous membrane in the pyloric region has been confirmed by studying different stomachs and it appears that probably in some gastric mucosae, there is an embryonic defect at the point where the two different histological structures meet. This gives place to a gap in the mucous membrane. If the gap is a genuine one it can be proved by the fact that the whole of it is protected by the presence of a semisquamous epithelial layer. The study of these pseudoulcers convinced us that if histologically they give a very abnormal picture they may have very little pathological meaning because (a) there is a very good protective layer present and (b) there is an absence of any cellular infiltration of the gastric wall which disagrees entirely with the pathological picture of inflammation.

After our description of the semisquamous epithelial layer which covers the normal gastric mucosa, and of the layer in different pathological processes it follows logically that the criterion of ulceration should be changed accordingly. The presence of an irregular mucous membrane with a very strong infiltration of cells, will signify an ulcer only if the area of mucous membrane is not covered by a semisquamous layer and there will not be an ulcer if this layer is present, independent of the condition of the mucous membrane. We should keep in mind that this pathology of the mucous membrane should be compared to the pathology of the skin, that is, as long as the stratum corneum is complete there is no ulceration independent of the condition of the other strata.

Carcinoma of the stomach. The carcinomas given to us from gastric resections were far enough advanced to have given clinical or roentgenological signs which warranted their resection. For this reason, therefore we have been unable to throw more light on the problem as to whether carcinomas always arise from an ulcer or whether they can arise with-

out any previous lesion of the semisquamous epithelial layer, the mucous membrane layer only being involved. In all our studies of carcinoma, except one, we have always found large areas of ulceration, but whether these were primary or secondary we are unable to say.

As a result of our investigations we are able to describe two histological pictures of gastric carcinoma which appear simultaneously in all the carcinomas studied so far. (a) Typical carcinomatous ulcers, in which case, in the crater of the ulcer can be found carcinomatous cells. The ulcer is not protected at all by a semisquamous epithelial layer and this is similar to the process found in the simple gastric ulcers (Fig. 16). (b) In the region between what appears to be normal mucosa and the carcinomatous ulcer, it can be seen that there are regions where the mucous membrane changes, and appears to pass from normal mucosa to carcinomatous mucosa, but the whole mucous membrane is protected by the semisquamous epithelial layer. This is the area where the carcinoma spreads toward the normal tissue (Fig. 17).

In a carcinoma which appeared to have a nonulcerative mucous membrane we found that after formaline vapor fixation and section that the mucous membrane was very disorganized but was covered by a well defined semisquamous epithelial layer. This layer showed areas of extensive infiltration and in some parts there appeared to be present some very tiny ulcers of the semisquamous epithelial layer.

On the whole this carcinoma was suggestive of a neoplastic process arising firstly from the mucous membrane itself without any previous degree of ulceration of the semisquamous epithelial layer. This is the only observation we have done, however in which it appears that the primary lesion is in the mucous membrane and there is only secondary involvement of the semisquamous epithelial layer (Fig. 18).

I cannot see any possibility of clearing up this problem, except for people like the medical legalists who may be in a position to study very early carcinomas from people who have been killed by accident, and who may have

early carcinomatous changes of the mucous membrane which have not arrived at the stage of giving clinical signs. Naturally this examination of the gastric mucosa must be carried out as soon as possible after death before auto-digestion has set in.

SUMMARY

We have described the pathology of the semisquamous epithelial layer in the preulcerative processes, the absence of the layer in the ulcer itself the aspect of the layer in the post-ulcerative lesion and also how this layer is necessary in the process of cicatrization. We

have studied the relation of the layer to gastric carcinoma.

Our investigations have enabled us to give evidence that the layer plays a very important part in the protection of the gastric mucosa as without it the mucosa is destroyed, and there is a picture of gastric ulcer. The layer is absolutely necessary for the healing and reconstruction of the histology of the gastric mucosa.

NOTES ON THE HISTORY OF RESUSCITATION IN THE MEDITERRANEAN THEATER OF OPERATIONS

HENRY A. BEECHER, Lieutenant Colonel M.C., A.U.S., Boston, Massachusetts

THE Mediterranean campaign lasted 30 months and was one of the longest undertaken by the United States Army since the Civil War. Tragic as this was in many ways, it did give the inestimable advantage of time to correct errors, time to introduce test and establish good practices.

THE TREATMENT OF TWO PATIENTS

Two years and many a medical *tour de force* are spanned by the following 2 cases. It is a long stretch from the Atlas Mountains, over the Apennines, to the Alps. Not only a treacherous enemy operating in a countryside all ways favorable to him, but mistaken concepts of treatment had to be surmounted and new procedures introduced in the slow journey that was made. There may be some value in recording why and how and when our practices became as they were at the end of the war.

TUNISIA

March 21, 1943

Infantryman H was wounded by a shell fragment and tagged at the Regimental Aid Station at 1100 hours, March 21, 1943 with the diagnosis of compound fracture of the left humerus and laceration of the left side of the chest.

First aid: Morphine grain $\frac{1}{4}$ was given at 1100 hours. Sulfanilamide dressings and a Thomas arm splint were applied. He was promptly sent to the Clearing Station where 1 c.c. tetanus toxoid was injected and 500 c.c. (3 units) blood plasma administered. His general

PO VALLEY

April 1, 1945

Infantryman R, age 26, was wounded by shell fragments at 1300 hours, April 21, 1945 with compound fractures of the left femur and of both ankles and a penetrating wound of the chest with hemothorax and multiple lacerations of the legs and the face.

First aid: In the Collecting Company at 1315 hours, 1500 c.c. (6 units) of blood plasma was given as were dressings, leg supports, and morphine grain $\frac{1}{4}$. He was evacuated to the Clearing Station where 20,000 units penicillin were in-

TUNISIA

condition was not described in his record.

Hospital entry: At some time in the afternoon he was evacuated to a Surgical Hospital. At 1715 hours his blood pressure was 110/70 with pulse of 120. More complete examination was carried out here than he had had previously. It revealed absent breath sounds and hyperresonance on the left. His abdomen was rigid and tender. At 1745 hours a further 500 c.c. (2 units) plasma injection was given. Fluoroscopy was then carried out. A fracture was found in the lower $\frac{1}{2}$ of the left humerus with lateral bowing present. There was increased density in the left chest with the mediastinum pushed over probably by fluid. A large foreign body was seen in the stomach region.

The chest wound was sutured. There was no evidence of "sucking".

At the time of the fluoroscopic examination the blood pressure was good and the pulse of fair quality. It was judged that the patient had a combined thoracic and abdominal wound with ruptured viscera and probable hemorrhage. Transfusion and immediate operation were decided upon. One 500 c.c. blood transfusion was given. The abdomen was opened through a long left rectus incision. This was accompanied by a gush of blood and air with

PO VALLEY

jected, 250 c.c. (1 unit) plasma was administered and because of his exceptionally poor general appearance 1000 c.c. whole blood was obtained from the adjacent field hospital and given. His blood pressure was 90/60.

Hospital entry: At 2100 hours. On arrival his blood pressure was not measurable. His face was pale but warm. The extremities cool, and veins collapsed. Shock was classified as severe. His blood volume was measured (see below). In the ensuing 4 hours he was given 500 c.c. (2 units) plasma and 2000 c.c. whole blood. His blood pressure had risen from 0 to 110/65. The pulse rate was 138. He received 25,000 additional units of penicillin. Operation was carried out at 0330-0600 hours. April 22 under intratracheal nitrous oxide oxygen. Guillotine amputation of the left thigh was performed. Débridement was made of the extremity and chest wall wounds with aspiration of 1000 c.c. blood from the right pleural cavity. Penicillin 25,000 units was placed in the chest. He was put on nasal oxygen. Subsequently the patient made an excellent recovery.

Laboratory notes: At 2200 hours, April 21. Hemoglobin 9.8 grams per cent, hematocrit 29, blood volume 5020. This

F. M. Report by Major (later Colonel) Howard E. Snyder (14)

From records of Board For The Study Of The Severely Wounded (6)

TUNISIA

Immediate respiratory difficulty. A 4 centimeter laceration of the dome of the diaphragm was found and closed. After this the patient's condition improved greatly. A 10 centimeter laceration of the stomach, each near the greater curvature was present, this was closed. It had been caused by a 1 by 2 by 3 centimeter shell fragment. The only other injury found in the abdomen was a small laceration of the spleen. This was not bleeding. Twelve grams of sulfanilamide powder was dusted into the abdomen and the incision was closed. Shortly after this the patient developed a sucking wound of the chest at the site of the entrance of the missile previously sutured. Closed drainage was established and the wound was packed tightly with vaseline gauze. The patient died at 2315 hours March 21.

Comment: The patient was clearly desperately wounded; he was resuscitated by 4 units of plasma and one blood transfusion. Although the blood pressure is recorded finally as normal, the pulse of rapid and only fair quality gives evidence of inadequate resuscitation. It is impossible to judge how serious the pneumothorax was that seems to have been the cause of death or whether a bilateral pneumothorax may have been overlooked however the failure to surmount accidents during and soon after operation is characteristic of the blood-out patient resuscitated by plasma, without adequate blood replacement.

PO VALLEY

is 19 per cent below his calculated blood volume normal. If corrected for fluids administered he had lost since wounding 76 per cent of his normal blood volume, and 35 per cent of his normal hemoglobin.

Comment: Blood plasma, 2250 c.c. (9 units) and 3000 c.c. whole blood were used here for resuscitation. (In addition, blood was used liberally in the postoperative period to overcome the acute anemia and to promote wound healing.) Penicillin was available here but not for the earlier case. The tremendous blood loss emphasizes how dangerous it would have been in this case to have attempted to get along on plasma alone. Oxygen was available and used.

While these figures are from those of the Board for the St. dy. I. T. 8. ly Wounded (6) careful measurements of blood volume were first made in the Theater by Lieutenant Colonel John D. Stewart and Captain Frank Warner. Observation on the Severely Wounded in Forward Field Hospitals with Special Reference to Wound Shock (2).

Most of the serious problems of resuscitation of the wounded are in fact problems of the treatment of shock. Shock, in turn is a disability of the circulatory system that parallels (is caused by) loss of effective blood volume and of hemoglobin. The major problem, then, is how can this loss best be overcome, at least to the point where the patient can withstand transport to and the necessary surgery at the most forward hospital. The account of resuscitation as dealt with here is, broadly speaking, chiefly a history of blood volume replacement therapy in the general management of the wounded man. The history of resuscitation in this theater can be epitomized in the innovations made and their consequences in a description of several changing trends. Some discussion of the goals sought and the errors it became necessary to avoid will clarify the reasons for the innovations.

While differences in terminology in organization in evacuation, in resources technical and human vary so from World War I to World War II comparisons are in most cases useless; however the organization and mission of Field Hospital 127 in France in 1918 are said to have been comparable to that of the 33rd Field Hospital in the Mediterranean Theater in 1943, so the following table can be used for the valid illustration of a point.

	Field Hospital 127 1918	Field Hospital 33 1943
Number of days included	7	30
Cases admitted	256	297
Deaths without operation	4	0
Deaths after operation	34	56
Total mortality rate	20.3 per cent	18.8 per cent
Operative mortality rate	5.8 per cent	18.8 per cent

The interesting point in the table is the fact that all patients were prepared for operation in the 1943 group whereas 41 or 16 per cent never were considered to be ready for surgery and died without operation in 1918. There are chances for serious error in this type of comparison but there can be no doubt that striking differences in surgical management are illustrated here and that the key to these is resuscitation.

GOALS SOUGHT

The final statement in Dickinson Richards's Harvey Lecture says, "The greatest mis-

BEECHER RESUSCITATION

take is to suggest, as some have done, that shock is a problem that has been solved (Certainly few therapeutic attempts can be said to be completely successful.) Dr Richards's point is a sensible one but there is another view that must be considered as well. In the report of the Board for the Study of the Severely Wounded, the statement is made

the results (of this study of battlefield casualties) have shown in a useful way what appears to be a quantitative relationship between blood loss and degree of shock long recognized but always in need of all the support possible in order to outride the ever recurring storms arising from suggestions that the cause of shock is mysterious and to be explained by toxins or the breakdown of some vague but vital force. To recognize the relationship of blood loss to degree of shock as a practical guide in treating patients is not to minimize the interest or the importance of the shock problems awaiting study, nor is it to undervalue the importance of the mechanisms involved in the production of shock but it is to emphasize the importance of applying the therapy we know to be effective. Too much preoccupation in the clinical treatment of patients with the unsolved problems of shock can have the indirect but very closely associated result of leaving the physician without access to adequate necessary equipment for applying the therapy well proved to be effective in the treatment of shock blood as needed. This was the unfortunate fact in Tunisia.

A shrewd estimate of the extent to which the patient has suffered from his wounds (15) is necessary for a correct appraisal of the therapy needed in order to enable him to withstand transport to the forward hospital. Once there his response to the journey and to subsequent therapy will give valuable information as to what support he needs to withstand the surgery necessary. When the patient has been rescued from the condition where organic damage may occur as a result of inadequate circulation a very important element in his care lies in the correct timing of resuscitative measures and of operation. These matters have been discussed by Beecher and Burnett (1944) (5) and by Beecher (3) 1945. Lalich (10) and Lalich and Mason (11) in detailed

reports described careful studies to aid in appraising the patient's condition and to guide in determining quantity and timing of fluid therapy as well as timing of operation.

INNOVATIONS AND THEIR CONSEQUENCES
TRENDS

*Plasma*¹ The early difficulties of resuscitation in Tunisia (described below) are directly attributable to a mistaken concept of the limits of usefulness of human blood plasma. While there is no need to dwell upon this fact, long since corrected, any account of resuscitation would not be complete without some reference to it.

A misconception. The use of plasma suggested by Ward (1918) during the last war, but the agent did not become available then. Presumably this suggested use grew out of the belief that the method of blood transfusion then available, plus the hazards involved, offered too great obstacles to the widespread use of whole blood for resuscitating battle casualties, hazards that were too great to be allowable.

In Ward's communication (19), which was in the form of a letter to the editor of the *British Medical Journal*, he said, "There is abundant clinical and experimental evidence that it is not the corpuscles that are wanted, but the ideal fluid for keeping blood pressure at the proper level. A man dying from hemorrhage is not dying from lack of hemoglobin but from draining away of fluid, resulting in devitalization and low blood pressure."

These incorrect remarks were followed by the sensible suggestion that trial of plasma should be made and *controlled with the same number of whole blood transfusions*. Apparently this was not done.

Plasma² was recommended in 1939 as "an ideal substitute for whole blood in the emergency."

(This article was written in Italy with little possibility of checking references. All care possible has been taken to insure accuracy of quotation of spirit as well as of word. If error of fact or wrong emphasis has been made in the references given, this can be attributed to the circumstances, and is deeply regretted by the writer.)

While one might have concluded from reading much of the literature of the period that the importance of hemoglobin had been forgotten, this was not everywhere the case. For example, Kilduffe and DeBakey (9) emphasized the importance of hemoglobin (p. 277).

gency treatment of shock and hemorrhage from war wounds, by Tatum, Elliott and Nasset (17) Many other references could be given along this same line but there is no reason to do so The changed point of view has been so well summarized by De Bakcy and Carter (8) It may be quoted here rather fully

Although the development of plasma has undoubtedly been a great contribution, its usefulness in shock therapy can now be viewed in proper perspective. Unfortunately, the early enthusiasm that accompanied this development was so forceful that it pushed aside sound clinical judgment and led to the widespread misconception that plasma could be used as an effective and complete physiologic substitute for whole blood in the management of shock in the seriously wounded. This misconception became so firmly entrenched in the minds of both administrative and professional personnel that it somewhat handicapped the organization and development of more effective measures for the management of shock. With increasing experience in the treatment of shock, it became more and more evident that plasma could not be used as a complete substitute for whole blood. It was found that while seriously wounded men could be brought out of shock with plasma they were frequently unable to withstand the life-saving surgery that was subsequently necessary. Superficially such patients appeared ready for surgery, but it was soon realized that this appearance gave a false sense of security for even movement of the patient, anesthesia, and other procedures in preparation for surgery often caused the patient to fall back into shock. It soon became evident that whole blood transfusion was essential for the proper resuscitation of these patients and that whole blood is the only therapeutic agent that will prepare seriously wounded patients to withstand the surgery that is essential for the saving of life and limb.

The now widely recognized misconceptions that plagued the early use of plasma should by no means obscure the remarkable value of the substance as a life saving innovation. It has superbly filled the need of supporting life while the patient is transported to a place where whole blood transfusion is feasible. It also is useful where blood concentration is present, chiefly in burns, in crushing injuries, and in some abdominal wounds. The shifting emphasis in the use of the agent is shown in the following section.

Plasma and whole blood. A detailed consideration of these agents will be presented by Lieutenant Colonel Eugene R. Sullivan in a history of the base blood bank. He also will

present a description of the available equipment for transfusing blood its inadequacies and shortages in the early Tunisian campaign responsible in part for the relatively infrequent use of whole blood during that period. A few sample figures may be given here.

In general, the records of the use of plasma are too inaccurate to justify detailed presentation. A few dependable samples of these are

Use of plasma in the Tunisian campaign is shown in the following II Corps report for the period 1 February to 31 March 1943: number of casualties needing plasma, 972; per cent of casualties needing plasma, 34.3; unit consumption per 1000 for the period, 320.

In a sample of 431 seriously wounded men admitted to the hospital in the II Corps, January 21 1943 to February 28 1943, 101 patients received plasma (total quantity not stated) and 31 blood transfusions were given. In March 561 patients were admitted to Surgical Hospital No. 48, 741 operations were carried out, 97 whole blood transfusions were given.

These data contrast with the following also from seriously wounded patients: (6) Pre-operative blood plasma, 3.08 units per man (based upon an average of 122 cases); blood plasma given during operation, 1.68 units per man (based upon an average of 10 cases); pre-operative whole blood, 1450 c.c. per man (based upon an average of 127 cases); blood given during operation, 1160 c.c. per man (based upon an average of 95 cases).

The average of these very seriously wounded patients thus received from the time of wounding until the end of operation 3 to 4 units of plasma plus 5 blood transfusions.

In a letter written by Lieutenant Colonel (now Colonel) Frank Berry, surgical chief of the 9th Evacuation Hospital to the Surgeon of the North African Theater of Operations on July 1 1943, the following data are of interest.

Date	Number of hostile casualties treated	Number of blood transfusions given	Ratio of transfusions to hostile casualties
March 1943	140	17	07.4
April 1943	1358	24	28.0
May 1943	207	27	14.7

BEECHER RESUSCITATION

This remarkable trend continued. In an average of the data from 8 evacuation hospitals for the first 100 days of the Italian campaign, beginning September 9, 1943, the ratio of transfusions to battle casualties was 1:4.5. For all Fifth Army Hospitals for January, 1944, the ratio was 1:2.4. The base blood bank was introduced in February and in March the ratio had changed to 1:1.9. The trend is rather strikingly shown in the figure. The rapid rise in the incidence of the blood used was due to two main factors: (a) realization that plasma alone was not adequate and that whole blood was necessary; and (b) increasing availability of the necessary organization and equipment for transfusion. The undramatic change shown between January and March of 1944, during which time the base blood bank began to function (February 23, 1944), does not justly characterize this important innovation. While it is true that blood in large volume was being obtained, before the base blood bank was established, from local institutional blood banks, from local emergency bleeding as needed and by borrowing from the British the generally greater safety and uniformity of the base blood bank is, of course, not shown in a graph such as Figure 1. Moreover, the ready availability of very large volumes of blood up to several liters for a given case is a very important consequence of the introduction of the base blood bank, emphasized by Lieutenant Colonel Sullivan's (16) observation that in the first 100 days of the Italian campaign the field hospitals cared for one-thirteenth of the battle casualties and used one third of the blood. A few of the very badly wounded used a disproportionately great volume of the blood.

Albumin Albumin was first used in the field in this theater by Beecher and Burnett 1914 (5). In some 200 patients no definitely significant untoward effects were observed. As expected on the basis of clinical trials in the United States, low blood pressure was elevated although transiently by the albumin. Clinically, one unit of albumin was found to be about comparable to one unit of plasma in its blood pressure elevating effect, notwithstanding the theoretically greater power of the

Fig 1 Showing increasing use of whole blood

standing the theoretically greater power of the albumin. The chief advantages of this agent center around its small bulk and ready availability for use in difficultly accessible situations where space and weight are at a premium.

'STABILIZATION' VERSUS RAPID PREPARATION OF BATTLE CASUALTIES FOR SURGERY

At about the time of the crossing of the Volturno River, when the fighting was quite heavy below Venafro, early in November 1943, a new point of view began to appear in the shock tents of the Fifth Army to the effect that too much urgency was exercised in the preparation of the wounded for surgery. After 2 or 3 months this view had lost its negative character and during the prolonged fighting before Cassino, in the early months of 1944 it came to be stated in a positive way. In effect what was said was this: "The wounded get along better if surgery is delayed even after the blood volume and hemoglobin and blood pressure have approached normal." Patients were said to profit by some thing vaguely described as "equilibration or stabilization." What it was that happened merely with the passage of time was never very clearly defined. "They just did better." And of course there is some basis for such a view, although hardly as it came to be em-

ployed. Anyone could see that seriously wounded men who had been bounced over rough roads in a long ambulance haul, resting poorly often in great pain as the result of movement frequently arrived with rapid weak pulse and low blood pressure. With nothing more than 10 or 15 minutes of rest the blood pressure would rise and the pulse improve in quality. The chief gains to be obtained by rest at this stage of the patient's treatment are usually achieved in about 15 minutes. On the other hand as stated elsewhere (3)

the wound has set several continuing processes in action there is bleeding and plasma loss from serous surfaces and into traumatized tissues. Contamination leads to progressing infection. With these and other drains upon him the seriously wounded patient must have constant external support by way of blood and plasma. If as a principle, one can say that the smallest quantity of blood and plasma should be used that is compatible with the patient's well being then early operation appears desirable on this basis. Unquestionably delay in operation necessitates the use of larger quantities of blood and plasma to maintain the patient on an even keel than otherwise is the case. A further point is important in this connection. It has been well established in the cases of peritoneal contamination encountered in perforated peptic ulcer that the mortality rate rises sharply with the passage of time. With the grosser contamination met in warfare this is probably also the case. The passage of time is against the patient's good.

Beecher and Burnett 1944 (5) proposed following a study of 2853 battle casualties at Cassino and Anzio from which the shock cases 72 were filtered, that surgery be undertaken as early as possible and as arbitrary guides suggested that when the blood pressure is swinging up and is not below 80 millimeters of mercury systolic and the pulse rate falling if the patient's skin is warm and of good color that he be taken at once to surgery and what ever further blood administration is necessary be given during surgery *surgery being considered an integral part of resuscitation*. The results of this policy in the 2853 patients referred to were excellent, and while the proposal caused considerable discussion and disagreement at first, it has gradually come to be accepted as a satisfactory general working principle.

ERRORS TO AVOID

Any history of resuscitation in this theater would not be complete without some mention of the errors it was found necessary to avoid. The usual ones involved in poor medical care need not be reviewed here such as poor splinting inadequate protection from weather and so on rather several things will be mentioned here that are either new or have received new emphasis in the campaigns in this theater.

Morphine overdose It very early became apparent in Tunisia that the half-grain (30 mgm.) morphine syrette was too large. Medical corpsmen in this campaign were permitted to administer morphine for the first time in the history of the United States Army. While some have attributed the difficulties with the half-grain morphine syrette to this fact, it was the general observation that medical officers seemed more often to be at fault in their over use of morphine than were the men.

In the cold wet early days of November 1943 it was repeatedly observed (2)¹ that patients whose peripheral circulation was sluggish as a result of either chilling or low blood pressure absorbed subcutaneous or intramuscular injections of morphine slowly or not at all. This *delayed morphine absorption* too often led to the conclusion that the patient, who naturally got no effect from the unabSORBED morphine, was resistant to the drug and a second or third half grain was injected. This added drug had disastrous consequences when simultaneous and rapid absorption of all of the morphine injections occurred after the peripheral circulation was re-established as a result of resuscitation and the application of warmth.

The Surgeon of the Fifth Army established the rule late in 1943 that corpsmen were not to administer more than half of a morphine syrette. In addition to this, a vigorous educational program and the appreciation of the possibilities of delayed morphine poisoning all led to a sharp reduction in the accident of overdose.

In a study (4) carried out chiefly on the Anzio beachhead, it was found on the basis of an extended factual inquiry that severe pain

¹This had also been pointed out year earlier in *chills disaster* (Cocconi Grove) *Ann. Surg.* 943, 17

BEECHER RESUSCITATION

is much less common in the severely wounded than had been supposed, and that those who wanted (in response to a direct question) further pain therapy even though no morphine had been administered for several hours were surprisingly few. It was observed that certain wounds, notably penetrating abdominal wounds, are far more painful than others, but that morphine is as likely to be given to a patient with little pain as to one with severe pain. The observation was made and subsequently confirmed throughout the Theater that the severely wounded are often in need of sedation of the barbiturate type that the use of a modest dose of a barbiturate will control in some cases manic behavior formerly attributed to pain, and in many cases will obviate the need for morphine. As a generalization, the wounded were found to need small doses of both a sedative of a barbiturate type and of morphine. It was found that *this combination would often accomplish what large doses of either agent alone would fail to do*.

Delay in evacuation. It was not until in the Italian campaign that it came to be generally appreciated that too much time was consumed and too much handling of the patient under taken by the too frequent insistence on an out of the ambulance checking of the patients at each stop along the evacuation trail. Not enough by passing of some installations was carried out in order to expedite the passage of the wounded man to the hospital where he could get emergency surgery. This problem is difficult to solve with the present evacuation system. Various suggestions have been made that this be critically reviewed and modified in the light of experience. It seems inevitable that men of little clinical experience must staff the forward (the collecting company the clearing station) installations. Perhaps something can be accomplished by education. It is more likely that a major step toward solution of the problem will occur only when the opportunities are reduced for these young and eager men to exercise their in some cases not yet adequately trained judgment, that is, only when one of the way stations is eliminated.

The rather constant average of a 5 hour interval from hospital entry to surgery in the case of the seriously wounded seems too long

It was shown (5) that this could be reduced to 2 1/2 hours but in general not enough progress was made in cutting down this time.

Overuse of plasma preceding hospital entry. Notwithstanding earlier views to the contrary the truly vital importance of hemoglobin has been established. The administration of plasma preceding hospital entry beyond the point where the blood pressure is elevated enough to get the patient out of the critical shock level, will lead to renewed bleeding and perhaps critical loss of hemoglobin. Resuscitation by plasma alone can give a false appearance of well being in the patient and a false sense of security in his doctor, preserved as long as the patient is not subjected to any strain. The true weakness of the patient was often revealed in the early part of the Tunisian campaign (where large volumes of plasma were used without adequate blood transfusion), as soon as any strain was put upon him such as that due to anesthesia and operation.

STUDIES INSTITUTED WITH A VIEW TO IMPROVING THE RESUSCITATION OF THE WOUNDED PATIENT

These studies can be grouped under five headings they have been reported in detail elsewhere.

The laboratory and clinical studies of Lieutenant Colonel John D. Stewart and Captain Frank Warner (6) those of Captain Joseph J. Lahch and Major James M. Mason, III (10, 11) those of Lieutenant Colonel Henry K. Beecher and Major Charles H. Burnett (5, 7) the observations of the Board for the Study of the Severely Wounded and finally the observations that grew out of astute clinical observations alone for example those of Major Luther H. Wolff and Captain Troger F. Adkins (20) on tourniquets and Major Luther H. Wolff and Captain Robert D. Beech (1) on gastric dilation.

Less planned but equally important to the patient's welfare were the countless and inspiring examples of ingenious resourcefulness and devotion to the patient's well being shown on all sides. Examples of these impromptu

Members of Board: Lieutenant Colonel Tracy B. Malloy, Florindo A. Simone, Henry K. Beecher, and Eugene R. Sullivan, Major Charles H. Burnett, Captain Seymour L. Shapiro, and Louis D. Smith.

studies are too numerous to describe but one or two may be mentioned. Captain William Weiss's efforts to devise an apparatus whereby air or oxygen could be administered under positive pressure was one example from the early days in Tunisia. His efforts to devise a satisfactory suction apparatus were finally successful when he passed a tube from the operating tent to the windshield wiper of a truck parked outside. Justly celebrated was Captain Werner Hoeflich's preoccupation with any wrecked airplane that he could get his hands on in order to get the parts necessary to build a workable positive pressure apparatus to be used in conjunction with a breathing bag (basket ball bladder) he had obtained. Captain W. R. Turnbow made many ingenious improvisations for the care and safety of the patient in the operating room.

THE VALUE OF RED CELL TRANSFUSIONS

THE large scale preparation of plasma during the recent war made available considerable quantities of red cell res-
sues. The value of red cell transfusions in the treatment of anemia was recognized first in England and later in this country. Through the Blood Donor Service of the American Red Cross, red cell suspensions were distributed without cost to civilian hospitals in several urban centers. Over 15,000 red cell transfusions were given in the Detroit area alone. Red cells were also generally obtainable and had wide use in hospital blood banks where plasma was processed. Through these experiences red cell transfusions for the treatment of anemia have become a well established therapeutic procedure.

Red cells may be given in their concentrated form or isotonic saline solution equivalent to the amount of plasma withdrawn may be added. The hematocrit of a concentrated red cell

suspension averages 85 to 95 per cent which means that about 10 per cent of the plasma remains behind. This is sufficient to allow such a suspension to run freely through an 18 or 19 gauge needle. The flow is facilitated by raising the height of the suspension and by occasional agitation. Because of the small amount of plasma present concentrated type O cells can be given safely to recipients of any blood group. As a precaution the recipient's serum should always be matched against the donor's cells before use. Some authors have pooled the cells from two or three type O donors thus giving the recipient a large transfusion without changing bottles. Red cells remaining from blood that has been drawn into citrate solution should be used within five days. It has been shown that addition of a 10 per cent solution of corn syrup will preserve red cell suspensions for 14 to 21 days.

The main indication for the use of red cell transfusions is to raise the oxygen carrying power of the blood in patients with anemia. When anemia is associated with shock or hypoproteinemia whole blood certainly is to be preferred. In such cases however, red cell suspension supplemented with plasma should produce the same effect as whole blood. Toward the end of the war the superiority of whole blood over plasma in the emergency treatment of hemorrhage with shock became well recognized. In this regard, it is interesting to note that, in recent experiments on dogs red cell suspensions were more effective than plasma in overcoming shock produced by a single large hemorrhage.

For the treatment of anemia, red cell transfusions are as effective as an equivalent amount of whole blood. A similar rise in the erythro-

cyte count and hemoglobin value occurs and the survival period of the cells are the same with both types of transfusion. In many of the reported series of cases, the percentage of adverse reactions are somewhat lower with cells than with whole blood.

There are certain advantages of the transfusion of red cell suspensions over whole blood. Probably the chief advantage is the factor of economy. Blood obtained from professional donors has always been expensive and the supply from friends and relatives is often limited. Thus many patients do not receive the amount of blood necessary to restore the erythrocyte count to normal during periods of stress. As there will continue to be a demand for human plasma, it would seem desirable to divide the cost of whole blood between the plasma and red cells. Both products would then be more available to low income patients. Another advantage of red cell suspensions is the fact that type O cells can be given to recipients of any blood type. Type O whole blood with a high agglutinin titer in the serum is a potential source of danger when used universally. The reduced volume of concentrated red cell suspensions as compared to the original volume of the whole blood from which it is obtained also has advantages. The cells from one to two liters of blood can be given over a period of several hours thus causing rapid and marked increases in the erythrocyte count. In some cases it is desirable that sufficient blood be given to raise the erythrocytes and hemoglobin to normal over a short period of time. The danger of overloading the circulation is an important consideration in patients with cardiac disease or with anemia alone. Deaths due to cardiac failure may result from the rapid administration of blood to a severely anemic patient. This danger is lessened with the use of concentrated cell suspensions.

In the average hospital over half of blood

transfusions are given primarily for the treatment of anemia. These patients would benefit equally from red cell suspension transfusions. Because of the expense and unavailability of whole blood it is not uncommon for sick patients to receive only one or two pints of blood regardless of the degree of anemia. If red cells were available at a low cost they could be used more freely than is the present practice with whole blood. Preoperatively and postoperatively the erythrocyte count and hemoglobin level could be maintained at normal levels regardless of the amount of cells required. In patients with iron deficiency anemia the hemoglobin can be raised rapidly with cell transfusions as the transfused cells die off the iron released becomes available for the formation of new erythrocytes. Spontaneous recovery of the anemia following hemorrhage or the recovery of pernicious anemia with liver therapy requires about six weeks. Convalescence is greatly hastened in such cases by the transfusion of the red cells from one or two liters of blood. Red cell transfusions are ideal for patients with aplastic anemia and other blood dyscrasias where the rate of blood formation is less than that of blood destruction.

It is needless to say that red cell transfusions just as whole blood should be given only when clear cut indications are present. In individuals over 60 years of age erythrocyte counts of 4.0 million and hemoglobin values of 12 grams fall within the normal range. Nothing is to be gained by raising the erythrocytes and hemoglobin over these levels. By so doing the tendency to cardiac embarrassment and thrombosis is increased. Patients with a low grade static anemia as from sepsis or azotemia are probably little benefited by temporarily raising the red blood cell count. The dangers of transmitting hepatitis, malaria and syphilis are present with cell suspensions as with whole blood.

At the present time, red cell suspensions are not easy to obtain. The discontinuation of mass blood donation to the armed forces for the processing of plasma has eliminated this source of cells. Further Red Cross lyophilized plasma has been given to civilian hospitals throughout the country. Therefore there is little demand for fresh plasma from which the red cell residues ordinarily would be available. When the present supply of Red Cross plasma is exhausted, there undoubtedly again will be an extensive processing of plasma and the red cells can be salvaged. The increasing use for various protein fractions from human plasma is another potential source of red cells. When red cell suspensions again become more plentiful they deserve general usage in the treatment of anemia.

HOWARD L. ALT

ANEMIA IN BURNS

WITH the treatment of burns becoming sufficiently advanced to make it possible to keep the deeply and extensively burned patient alive the anemia of burns is being encountered more frequently and of a severity often incompatible with life. Previously accepted as rare and of little concern, it has emerged from obscurity during the period of war research to be defined to the extent that it should be predicted and forestalled.

As a result of recent study of the anemia of burns, more causes for it have been found than were heretofore considered. To external blood loss have been added the effect of heat upon the circulating red cell, the internal disappearance of cells presumably the result of widespread infection and inhibition of red cell regeneration. The obvious loss of blood from the granulating wound surfaces¹ and the

occasional finding of blood in the stools² had made it reasonable to ascribe the anemia to external blood loss. The presence of hemoglobinuria in victims of the Coconut Grove fire suggested to Shen and Ham³ the probability of an internal breakdown of red cells as well. In these and subsequent patients they observed an increased fragility and abnormal spheroidal shape of the circulating red blood corpuscles. On the basis of experimental evidence in human and dog blood these abnormalities were ascribed to the effects of the heat upon those cells circulating in the periphery.

The findings of Shen and Ham have been elaborated by Brown of the Burns Unit under Colebrook at Glasgow⁴; the increased fragility of the red corpuscles was found to be limited to the hours immediately following the trauma. The increase was gradually supplanted by a subnormal fragility which lasted until the tenth day the normal level of fragility was passed at the thirty-sixth hour. The subnormal fragility was ascribed to the disappearance from the circulation of the more fragile cells. It was postulated from experimental observation that the volume of cells hemolyzed could amount to as much as 8 per cent of the original number present before trauma. The hemolysis of fragile cells was also correlated with the extent of the burn. Although increased fragility was found in patients with less than 15 per cent of the body surface burned, it was only in patients with burns of more than this extent that a decreased fragility and a subsequent anemia were discernible.

An internal disappearance of red cells has also been demonstrated beyond that which can be accounted for by the hemolysis due to the burn trauma. Investigators of the Har-

¹HARRISON, H. N. *Surgery* 1938, 3, 608.

³COLEBROOK, L., et al. *Studies of Burns and Scalds (Reports of the Burns Unit, Royal Infirmary Glasgow 1942-43)*. Medical Research Council, Special Report Series 249. London: His Majesty's Stationery Office, 1944.

vard Medical School and the Massachusetts Institute of Technology using precise methods for determining the red cell mass and pigment excretion have observed a massive disappearance of red cells in deeply and extensively burned patients in the first two months after injury.¹ The maximum loss observed was 318 cubic centimeters of packed red cells per day for the six days following injury. This loss was observed in a healthy young woman with a burn of 78 per cent of the body surface, 45 per cent of the surface being of full thickness destruction. From the fifteenth to the seventy-second day this same patient was found to be losing cells again and at the rate of 65 cubic centimeters of packed cells per day. Another severely burned patient, from the tenth to the eighteenth day after injury lost 191 cubic centimeters per day and from the nineteenth to the thirty-sixth day 74 cubic centimeters per day. The internal disappearance was not observed in patients with extensive partial thickness or only circumscribed full thickness burns and unexpectedly not in two elderly deeply and extensively burned patients who did not die until the eighth and tenth days after injury.

The origin of this internal loss or disappearance of red cells is obscure but since it appears only in patients with extensive deep burns, it is tempting to ascribe it to the infection of mixed organisms characteristic of the full thickness burn wound allowed to be fallow and separate its slough spontaneously. That it is not due to the trauma sustained by the red cells at the time of the burn is proved by the observation that cells transfused into the patient after the injury partake equally in the disappearance. For this determination tagged cells were used prepared by injecting volunteer donors with radioactive iron.

The fate of the vanishing red cells is also obscure. Although an excess of urobilinogen was found in the urine during the periods when the red cell mass was observed to be shrinking the excretion products of blood pigment accounted for but 10 per cent of the loss. The recent work of the Menkins² and of Wintrobe and his collaborators³ suggests that the red cells and hemoglobin may be disintegrated at the inflammatory barrier.

The possible failure of red cell regeneration as a contributing cause of the anemia has also been explored by injecting radioactive iron into the burned patients.⁴ The rate of red cell formation was judged by the rise in the level of radioactivity of the circulating red cells. In an unburned normal person 70 per cent of the radioactive iron injected is elaborated into the hemoglobin of the circulating cells at the end of eight days. In a patient with a severe burn the red cell formation may be reduced to less than a third of the normal.

The early anemia due to initial hemolysis and massive internal red cell disappearance must be differentiated from the pseudoanemia of hemodilution which occurs from the third to sixth day after injury. The pseudoanemia is due to an enlarged plasma volume and results from a resorption of wound edema at a rate in excess of renal excretion. The distinction between the true and false anemias is important from the point of view of therapy.

The treatment of the true anemia of burns is whole blood transfusions; the circulating red cell mass should be maintained as nearly replete as possible at all times. The treatment of the false anemia of burns is the curtailment

SURGERY, GYNECOLOGY AND OBSTETRICS

of fluid therapy Transfusion of the patient with a false anemia results in a further increase in blood volume and the danger of cardiac insufficiency and pulmonary edema. In the effort to forestall the true anemia of the extensively and deeply burned patient it is tempting to inject large volumes of whole blood in the first days after injury with the understanding that the blood given in the initial hours would be a part of the therapy for the burn shock. Whole blood and saline solution instead of plasma have been recommended by Moyer and associates for the treatment of burn shock¹. Should the anticipated red cell destruction and anemia not be

realized, however, the excessive red cell mass will prove embarrassing. To ascertain, therefore, whether whole blood is indicated periodic measurements of the plasma volume and red cell mass are required. The dye technique for these measurements is simple, accurate, and well established, the hospital caring for burn patients should provide the surgeon with this laboratory aid.

Although we are able to predict and forestall the anemia of burns, we still do not know how to preclude the continued red cell disappearance. Because the infection of the wounds is possibly an instrument of red cell destruction, expeditious closure of full thickness wounds and administration of polyvalent chemotherapy are not amiss.

DID CHOLERA DEFEAT CUSTER

PAUL R. HAWLEY M.D., Major General U.S.A. (Ret.) Washington District of Columbia

ON October 31 1848 the Swanton sailed from Le Havre with 280 steerage passengers, most of them German emigrants, and arrived in New Orleans on December 17 having lost 16 of her passengers directly to her dock and discharged cargo and passengers. The next day one of the surviving passengers was admitted to Charity Hospital with a frank case of Asiatic cholera. Other cases followed in rapid succession the disease spreading among the inhabitants of the levee district. In less than 2 weeks there were from 40 to 50 deaths from cholera per day in New Orleans.

Within an incredibly short time practically every packet boat on the Mississippi River was infected and the epidemic spread to Memphis, St. Louis, Nashville, Louisville, Wheeling and Pittsburgh. On Christmas day 1848 victims of the disease were removed from a river boat in Cincinnati and taken to the General Hospital. During the winter weather sporadic cases occurred among the local population in Springfield, but, when the weather turned warmer in Spring the disease burst forth in epidemic violence to disappear in the Autumn. It reappeared in June 1850 but with diminished fury.

For more than 25 years after the opening of the Santa Fe Trail in 1822 hostile Indians menaced its travelers. Along its middle reaches in what is now the State of Kansas the Pawnees were the fiercest but the Kaws who inhabited the valley of the Kansas River (about and north of the present Council Grove) while not warlike were assiduous cattle thieves and made frequent raids upon the wagon trains passing through their locality.

Fort Atkinson was established in 1850 on the Arkansas River about 6 miles above the site of

the present Dodge City. Its garrison afforded some protection in Southwestern Kansas, but the nearest Army post to the east was Fort Leavenworth on the Missouri River, almost 400 miles distant by trail. The Kaws, therefore were relatively free to plunder unguarded wagon trains.

The discovery of gold in California greatly increased the traffic over the Santa Fe Trail and the thievery of the Kaws grew apace. Being unable to protect this section of the trail from his base of operations at Fort Leavenworth the Commanding Officer of the First Dragoons recommended to the War Department on July 31 1852 that another Army post be established 'at or near a point on the Kansas River where the Republican fork unites with it.' Acting upon this recommendation the Secretary of War, Mr. Jefferson Davis, directed that a Board of Officers be appointed to select the site for a new post in the vicinity of the fork of the Kansas River and late in the Autumn of 1852 a company of the First Dragoons escorted this Board to the spot where the Smoky Hill and Republican Rivers join to form the Kansas River.

It is interesting to note in passing that the temporary camp pitched there was named Camp Center because these officers knew at that early date that they were not far from the geographical center of the United States. That the Coast and Geodetic Survey of the United States was sufficiently accurate in 1852 for such a close approximation is surprising. For many years the monument marking the geographical center of the United States stood within the easy throw of a stone from the junction of the Smoky Hill and the Republican Rivers but later refinements in the survey have located the point about 100 miles away.

After the favorable report of the Board was approved and money was appropriated by the Congress, the construction of temporary buildings was begun at Camp Center. After the death of

Brevet Major General Bennett Riley in June of 1853 the new post was given the name of Fort Riley. The Congress that adjourned on March 3, 1855 appropriated funds for the expansion of the post with permanent buildings and the contract for this work was let to the firm of Sawyer and McIlvain, of Cincinnati. This firm prepared the millwork, procured the hardware and collected the artisans in Cincinnati, and shipped all by river boat to Fort Leavenworth, whence they were transported to Fort Riley by wagons. The Board had reported an ample quantity of good building stone at the site.

Work commenced on the new construction early in July 1855. Before the end of the month there were 2 deaths from a disease very like cholera. On the first of August the epidemic began in earnest. There were several deaths each day and the presence of Asiatic cholera was no longer in doubt. Panic seized the camp. The Constructing Quartermaster died of the disease. Workmen opened his safe with explosives, divided among themselves the gold it had contained for their pay and scattered over the plains. The Army doctor, fearing for the safety of his wife and family, deserted his post and drove away with them in an ambulance. For this he was tried by court martial and dismissed from the service.

The epidemic burned itself out rapidly, its fuel being depleted by death and desertion. Convalescents regained strength and were reinforced with new recruits from the East. Work was resumed and the post completed without further incident. Some of the survivors of the epidemic remained as permanent employees of the post.

George Armstrong Custer was graduated from the United States Military Academy on June 24, 1861, at the age of 21 years, and was commissioned a Second Lieutenant of the Second Cavalry, United States Army. Less than two years later he was a Brigadier General and within another year was a Major General commanding a Cavalry Division.

The surrender at Appomattox found Custer not yet 27 years old, a major general whose only future in the Army was a garrison life on a frontier post with occasional brushes with small bands of Indians. At that he fared far better than many of his older comrades who had served with distinction in the war. One of the new Regular regiments created in the reorganization of the Army was the Seventh Cavalry, and Custer was given the permanent grade of lieutenant colonel of this regiment—a grade which often required 30 years

to reach in the peace-time Army. Furthermore, the colonel of this regiment was employed almost all the time on detached service, and Custer held uninterrupted command of the regiment.

Until the Spanish American War the Army maintained the system of brevet rank in lieu of medals for distinguished service. The only military decoration was the Congressional Medal of Honor and achievements not warranting this decoration, and some that did, were recognized by conferring a brevet rank upon the officer. A brevet rank was, for practical purposes, only an honorary rank. Thus a captain could be brevetted, for successive deeds, a major, a lieutenant colonel, and even higher while remaining a captain. His command authority continued to be that of a captain, but he took precedence among captains by virtue of the date and grade of his brevet rank.

With his reduction to the permanent rank of lieutenant colonel in the demobilization of the war time Army Custer retained his brevet rank of Major General. It is necessary to remember this in order to understand the administrative maneuvers that occurred when the selection of a commander for the expedition against the Sioux was under consideration.

The year 1867 found the newly organized Seventh Cavalry stationed at Fort Riley, Kansas, under the command of Custer. Garrison routine was broken by occasional forays against hostile Indians. Custer employed the slashing cavalry tactics of the period and was uniformly successful—on the surface, at least—in his encounters with Indians. His favorite method of attack was a mounted charge through the Indian camp, launched before the warriors had recovered sufficiently from the surprise approach of the troops. It has been alleged that rarely was a living creature—braves, squaws, or papooses—spared in these encounters.

During the summer of 1867 when the Seventh Cavalry was on an Indian-hunting expedition in what is now Western Kansas and Eastern Colorado, Asiatic cholera again broke out in Fort Riley. There was the usual panic that accompanied the appearance of this terrifying disease. The news reached Custer in the field, and he became alarmed over the safety of Mrs. Custer who was living at Fort Riley.

Upon his own authority, he left the regiment in command of the next senior officer, and, with an escort of 100 troopers, Custer set off post-haste in a mule-drawn ambulance for Fort Harker near the site of present Ellsworth, Kansas, whence he boarded a train for Fort Riley. For this violation

1003 HAWLEY DID CHOLERA DEFEAT CUSTER

of the Articles of War, charges were preferred against Custer and he was ordered to appear for trial by a general court martial.

The initial charges were that he had without authority left his command—in other words, had been AWOL. But now that the hitherto untouchable favorite of higher commanders had made himself vulnerable, past offenses—the knowledge of which had rankled in many breasts for some months—were brought to light. Additional charges were preferred. It was alleged that, during the dash across the plains to Fort Harker his small rear guard of troopers had been attacked by Indians and that he had pushed on without sending assistance back to them. There were casualties and the question was raised as to whether or not some of the living troopers did not fall into the hands of the Indians.

It was an unpardonable sin in the unwritten code of Indian warfare to abandon any living soldier to the mercy of the Indians. The whole force must be risked to save a single trooper. Yet Custer was to be accused, although not formally of a repetition of this offense at the Battle of the Washita a little more than a year later. There it was said Custer abandoned Major Elliott and a detachment who had been cut off while making a flank attack in obedience to orders.

Whether or not these accusations were true—and there can be no doubt that they were true at least in part—and whether or not, if true, the acts were justifiable, the respect and affection of a considerable proportion of the regiment were alienated. So long as Custer commanded it thereafter the Seventh Cavalry was not a happy outfit.

And then there were incidents on the march of the regiment to Colorado. The Morning Reports of the least, quite unsavory. The period are evidence of an unhealthy state of discipline in the regiment. There was scarcely a night during which one or more of the troopers did not desert on the trackless plains infested with hostile Indians, armed only with their carbines and a few rounds of ammunition. To desert under such unfavorable conditions one must have compelling reasons.

One afternoon the regiment made camp with several hours of daylight remaining. Without waiting for the protection of night, some ten or twelve troopers "went over the hill." A few took their mounts others went on foot. Their deserture was soon discovered, and some of them were seen in the distance. A specification of one of the court-martial charges against Custer alleged that he ordered the Officer of the Day to pursue the deserters with the guard and to shoot them down

without quarter. The guard set out at once. A few of the deserters were captured and brought back to camp. Two of these had been shot and were seriously, though not critically wounded. It was further alleged that Custer directed the wounded men to be placed in a wagon, and that he forbade the regimental surgeon to go near them or provide any medical care for them.

The court martial convicted Custer and sentenced him to loss of rank and pay for one year. Custer served this sentence and rejoined his regiment in 1868, but the reputation of the "boy general" was tarnished. The effect of this humiliation is apparent during the remaining years of his life. He had been, in his own estimation the victim of persecution by small jealous competitors. The giant had been severely wounded, and the wound festered leaving an ugly scar. His pride had been leaving an ugly scar. This scar could be made less noticeable less disfiguring, only by republishing his reputation to a brilliance that would blind the public to the defect.

Custer's first effort to re-establish his importance was unsuccessful. His second effort was fatal. His first opportunity came when the scandal of President Grant's administration exploded. Belknap, Grant's Secretary of War, was accused of selling positions, among them the positions of post trader on Army posts. The post trader's store was the prototype of the post exchange. It often was a private concession, the profits of which were huge. Custer accepted the invitation of the Senate Investigating Committee to testify against the Secretary of War. Here was his opportunity to have revenge on the "brass hats" in the War Department—and he made all that he could of this opportunity.

But all that he could was not enough. He knew little of his own knowledge. His testimony was mostly hearsay, and would not have been admissible under any rules of evidence. On the one point on which he testified as having personal knowledge he was wrong and afterward had to retract his testimony. But he had taken advantage of the opportunity to release some of his spleen. This was in March 1876.

President Grant, never condoning dishonesty nor protecting malefactors, nevertheless was not pleased with this gratuitous attack upon one of his cabinet officers. Especially did he resent such conduct upon the part of an officer of the Regular Army—and more especially because it was apparent that the intent of the attack was merely to smear one of his appointees rather than to offer any acceptable evidence of malfeasance. The

President, however took no action at the time. But he remembered and he did not have to remember very long

In 1868, the United States Government entered into a treaty with the Sioux Nation which guaranteed the Indians a large territory, in what is now the Dakotas, to have and to hold in perpetuity. No white men would be permitted to encroach upon it. This land was not considered valuable to or particularly usable by the white man, and there was no reason why the Indian should not have it in exchange for his promise to relinquish all claims to much more valuable lands elsewhere.

But unfortunately it was not known at the time that there was gold in the Black Hills. When this was discovered, the situation was altered. The white man had been "gypped." The fact that he had not known of the presence of the gold when he signed the treaty obviously made the treaty null and void. Any lawyer could prove that.

So with the discovery of gold, the whites rushed to the Black Hills. The Indians protested this treaty violation to the Government but the Government was deaf. So the misguided Indians decided to take the matter into their own hands. Any white could have told them that this was a mistake, but the obstinate Sioux were in no mood to listen to reason.

It is not necessary to describe the several tribes of Indians that constituted the Sioux Nation. It is only necessary to point out that there were eight principal tribes in the Nation, and that allied with these were the separate tribes of Cheyennes and Arapahoes. The social organization of the Indian was not sufficiently developed to permit of either large or permanent alliances. So it is a measure of the intensity of the Indians' resentment of this injustice that they were able to perfect an effective alliance of many tribes, and to hold it together for a considerable time.

Two great Indians were largely responsible for the success of the alliance—Sitting Bull the Hunkpapa medicine man, and Crazy Horse, the Oglala warrior the greatest tactician ever produced by Indians. Our distorted histories have created the common misimpression that Sitting Bull was the great warrior chieftain of the Sioux. This is not true. He was their great demagogue. But whenever there was any fighting Sitting Bull repaired promptly to his tepee and occupied himself in making medicine. It is doubtful that his name derived from his posture and his professional incantations, but it is certainly a coincidence.

Active resistance on the part of the Indians commenced in 1875 when they began to commit a series of what, in recent times, are known as overt acts. They roamed beyond the borders of the reservation—their own reservation, within the borders of which the white men were roaming in violation of the treaty. They murdered they pillaged. They were fighting an undeclared war.

The situation worsened steadily until in the spring of 1876 the Government decided it could no longer ignore such open rebellion on the part of its wards. An expedition was planned, the purpose of which was to quell the uprising and force the Indians to return to their reservation.

This expedition was planned to consist of three columns of troops: a column under Crook to move northward from Fort Fetterman on the North Platte River (in what is now Converse County Wyoming); a column under Gibbon to move eastward from Fort Ellis (in what is now Meagher County Montana); and a column under Custer to move westward from Fort Abraham Lincoln, located just across the Missouri River from Bismarck, North Dakota.

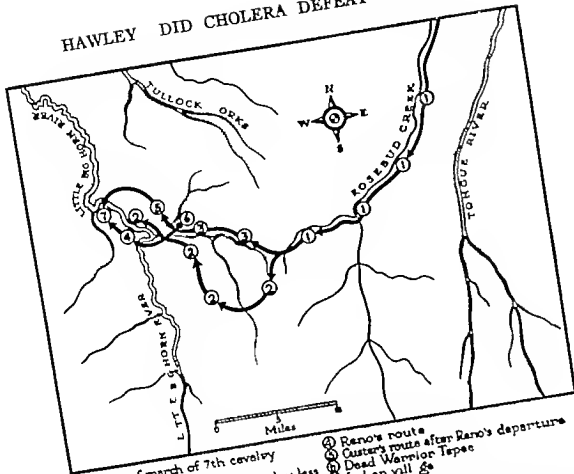

The plan was submitted to President Grant. He approved the plan but with one important exception. Custer would not be permitted to command any part of the expedition. In fact, he would not even be permitted to accompany his regiment on the expedition. The President had had enough of this publicity hound who thought nothing of embarrassing his Commander-in-Chief in order to promote his own reputation. The chicken of the testimony in the Belknap case had come home to roost.

General Alfred Terry was selected to command both the expedition and the column from Fort Abraham Lincoln. Custer made frantic efforts to be reinstated but only after the kindly intercession of General Terry did the President relent, and then only in part. Custer could go along in command of his Seventh Cavalry but he could not command a column—although his rank might entitle him to the command of the eastern column under the over-all command of Terry. Thus Custer's escutcheon was marred by another spot—and such spots were intolerable to George Armstrong Custer. This one, too, must be polished out at the earliest opportunity.

The eastern column left Fort Abraham Lincoln on May 17, 1876. By the 10th of June it had reached the Yellowstone River at a point not far from the location of present Miles City, Montana. Terry had made contact with Gibbon and began to plan the further operations. Crook had not yet been heard from—and was not to be heard from

for some time because Crazy Horse with a well armed well-controlled force was to meet Crook's column on June 17 and treat it so roughly that it had to turn back to camp to lick its wounds.

The location of the Indians had not yet been discovered and Terry ordered wide reconnaissances of the area. Custer's cavalry searched many square miles during the next week. Some traces of Indians were found but no Indians. By June 21 Terry had enough information to prepare further plans. Gibbon was to cross the Yellowstone River and march up the Big Horn and Little Horn valleys. Custer was to lead the Seventh Cavalry up the valley of Rosebud Creek to ascertain the direction of an Indian trail which had been previously reported.

Terry's orders to Custer were in writing. They were clear. If this Indian trail led across the divide into the valley of the Little Big Horn Custer was not to follow it, but was to continue on southward for the dual purpose of exploring the area of the headwaters of the Tongue River and of cutting off the escape of any Indians that might be finished by Gibbon as he marched up the Little Big Horn. After reconnoitering the upper reaches of the Tongue, and then only Custer was to turn westward cross the divide, and march down the Little Big Horn toward Gibbon. Estimating the time

and space factors for both forces, Terry expected Custer and Gibbon to meet in the Little Big Horn valley late on June 26 or early on the 27th.

Custer set off on June 22 with his entire regiment of twelve troops of cavalry—approximately 600 strong—and with some forty friendly Indian scouts. Before they left Terry offered to reinforce the Seventh Cavalry with a Gatling gun battery and four additional troops of cavalry from another regiment. But Custer declined the offer—an action which seems most significant in the light of the subsequent events. Was it that Custer had already decided to do the job alone not sharing the glory with anyone?

By the evening of the 24th Custer had found the Indian trail he was seeking and had also learned that it did cross the divide to the valley of the Little Big Horn. His next duty was clear. He should have reported this fact to Terry by courier and continued his reconnaissance to the south. But here was the opportunity to show the world that George Armstrong Custer assisted only by his own regiment of cavalry was more than a match for all the Indians on the plains. Why should he share the glory with Terry, Crook and Gibbon? He would show the President, the War Department, and all the people who had persecuted him in the past, just how unjust they had

been—just how greatly they had underestimated him. He would destroy the Sioux alone and on aided. The Lord had delivered them into his hands, and who was he to defy the Lord by passing up this opportunity to reinstate himself as a national hero?

So at once during the hours of darkness, the Seventh Cavalry began following the Indian trail leading into the Little Big Horn valley. Custer halted the regiment in the early hours of the morning until his Indian scouts could send him more information. But it was daylight before the Indian camp was located. Custer's previous experience had taught him the inestimable advantage of surprise—to steal upon a camp in the night and deliver a smashing attack in the early dawn before the Indians were even aware of his presence.

Should he now conceal his command during the daylight hours of the 25th approach stealthily during the night, and deliver his attack at dawn on the 26th? His military judgment said yes. But there was the possibility that Gibbon would have arrived by the morning of the 26th—and sharing this providential opportunity with Gibbon was unthinkable.

The regiment resumed its march in the day light. At noon Custer halted. He ordered Captain Benteen, with three troops, to make a reconnaissance to the left of the direction of march of the main body. The orders given Benteen were vague and they were further confused by additions and amendments. Benteen afterward testified before a Court of Inquiry that a strict interpretation of his orders would have required him to continue his reconnaissance until stopped by the Pacific Ocean but, fortunately, Benteen interpreted them reasonably rather than strictly.

Benteen left with his troops, and the main body continued along the Indian trail. Indian signs were fresher and there were more of them. About 2:00 p.m. the column reached a tepee beside the trail in which the body of an Indian warrior lay on a bier. Custer never knew it but this was one of Crazy Horse's braves who had died of wounds on the way back from the fight with Crook. In fact, the trail had been made by Crazy Horse's force.

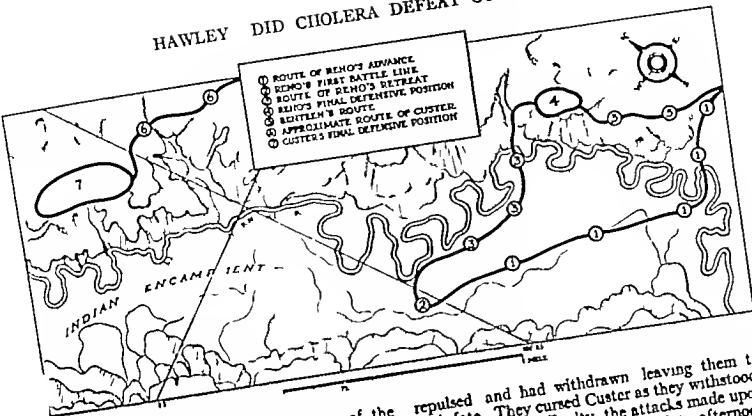

It was at about this point and this time that the Indian camp became visible in the Little Big Horn valley some five miles distant. Because of the rough terrain intervening little could be seen of the details of the camp or of the ground over which any attack would have to be made. No further reconnaissance was made, however. With no information as to the strength and disposition

of the Indians, and with practically no information as to the terrain Custer issued orders for the attack. Major Reno was to take three troops and advance rapidly toward the cloud of dust that marked the Indian camp and, as soon as he came within striking distance, was to charge the camp. Other than telling Reno that his little force would be "supported by the whole outfit," Custer gave him no information of his further intentions. Reno did not inquire because the relations between him and his commander were strictly official. There were many in the Seventh Cavalry who had never forgiven Custer for abandoning their comrades in previous Indian fights and the regiment was torn with schisms.

Without further word Reno set out. He had three miles to go to reach the Little Big Horn River, and this he made at a fast trot. He forded the river about three miles above the Indian camp and stopped to water his horses. Then he reformed his command in the fringe of trees along the river and began his advance on the camp. Two of his troops were in the front line with one following closely in reserve—a brave little band of 122 marching on several thousand Indians. After clearing the cover of the trees, they took up the trot. Soon hundreds of Indians were riding to their left, and firing on them from the flank and rear. Already Reno was confronted by many more Indians than his own little command numbered, and he was nowhere near the Indian main body. Reno halted, formed a dismounted battle line and assumed the defensive. He was driven back by hordes of Indians and, as he fell back, he pivoted on his right flank so as to place the river and the trees on its bank to his rear. The fighting increased in intensity. More and more Indians joined in. The cavalry were losing men rapidly, and it was apparent to Reno that they would all be lost if they continued the attempt to hold this position. He ordered the survivors to mount. The Indians dashed in and fired volleys at point blank range, throwing the troops into confusion. Reno ordered a charge into the mass of Indians. In the confusion, seventeen men were left in the strip of woods but the rest, led by Reno, literally cut their way through solid masses of Indians and then fled, with horses at a dead run, toward the ford at which they had first crossed the river.

But the Indians kept heavy pressure upon the right of the fleeing column, and it was unable to reach the ford. The troopers were forced across the river about a mile below the ford and they assembled on a nose of the bluff on the right bank of the river—here to make their last stand which it seemed evident, would be of short duration.

HAWLEY DID CHOLERA DEFEAT CUSTER

No sooner had they reached the top of the bluff than they saw a column of cavalry approach ing over the high ground. Was this Custer? Was he belatedly coming to their rescue? No it was Benten with his three troops. It was a joyful reunion, in spite of the fact that it didn't alter the situation very much. Even with the addition of Benten's command they were still outnumbered twenty to one by the Indians. It could be only that more of them would perish.

"Where is Custer", they demanded of Benten. But all Benten knew was that he had been recalled from his reconnaissance mission by a laconic message from Custer scribbled on a scrap of paper. Benten, come on. Big village. Be quick. Bring packs. Upon receiving this, Benten had turned back until he struck the Indian trail and had then followed it toward the valley. He had not even waited for the pack train to catch up. Hearing the sound of the firing in Reno's fight, he had cut across the country in its direction. He had supposed it was Custer with the rest of the regiment, who was engaged with the Indians. Where, then, was Custer? Had he abandoned them as he had abandoned parts of his regiment before? No one doubted that this had happened.

Shortly after Benten's arrival other sounds of firing were heard from the direction of the bluffs on the right bank of the Little Big Horn some two or three miles farther down stream. The firing was at first heavy but gradually lessened and finally ceased. Now the besieged band was certain of what had happened they decided that Custer had attacked the Indian village, had been

repulsed and had withdrawn leaving them to their fate. They cursed Custer as they withstood sometimes with difficulty the attacks made upon their little stronghold during the late afternoon and evening.

It was a long night. There was much commotion in the Indian village, but eventually this quieted and except for occasional shots fired by Indian snipers, the only sounds were the groans of the wounded and the muttered curses of the embittered soldiers while they waited for their last dawn.

As soon as the hilltops were light, the Indian attack was renewed with vengeance. Reno's little command was completely surrounded and the Indians were firing on them from all sides. When the Indians crept close enough to make their fire too accurate, the soldiers drove them back with courageous counterattacks.

This bitter fighting continued all morning. If Custer didn't come soon, all would be over. The arrival of the pack train in the late afternoon of the previous day had brought them plenty of ammunition but their water was exhausted and the sun was terribly hot. A few men, at very great risk crept to the river to fill their canteens but these dribbles were only enough for the wounded. The end was in sight.

Suddenly around noon the Indians broke off the attack. The soldiers could see the tepees being struck in the Indian camp. Pony herds were collected and the large force of Indians with their squaws and children, started slowly westward toward the Big Horn Mountains and gradually disappeared in the distance. That they were mysti-

fied by this sudden tactic of the Indians in no wise lessened the rejoicing of Reno and his men

Let us return to Custer as he sat on his horse near the Dead Warrior Tepee as it became known in history in the early afternoon of the 25th. He has already dispatched Benteen with three troops on a vague mission. He has just made his decision to attack and has started Reno with three troops more, on his mission. One troop is some distance to the rear guarding the pack train that is unable to keep up with the pace Custer set in his impatience to close with the Indians before Gibbon arrives. This leaves Custer only five troops—a total of about 225 officers and men.

He has divided his total force three ways—and this in the face of an enemy of unknown strength on ground that no one in his command has ever seen. It is not a happy situation. Perhaps Custer is not particularly pleased with it. But the urgency of the moment, the overwhelming desire to accomplish this coup without assistance carries more weight than the evident danger of disaster.

What Custer intended to do with the five troops, which he retained under his own control, can only be surmised. But the circumstantial evidence is rather convincing that he intended to move it down the right bank of the Little Big Horn (instead of crossing the river where Reno crossed) until he was opposite the Indian camp and there to ford the stream and charge into the village in a direction at a right angle to the direction of Reno's attack—in technical language an enveloping attack for which Reno should furnish the holding attack except that the mission given Reno went well beyond the usual scope of a holding attack.

Custer moved to carry out some such a plan. He soon found his column in very rough terrain, in which the high ground near the river was badly cut up by deep gullies, the axes of which were perpendicular to his line of march. This slowed up his march very much and explains why Reno had been fighting for more than one hour before Custer closed with the enemy.

For another reason the plan was doomed to failure from the start. Adjacent the Indian camp the right bank of the river was a steep cliff and the horses could never have reached the stream at this place. But Custer did not know this until too late—if indeed, he ever knew it. He made no reconnaissance and he knew nothing of the terrain.

As Custer's column was struggling across the narrow gullies in the hills opposite the Indian camp it was struck without warning by an overwhelming force of savages under Crazy Horse. From the mute evidence left by the bodies of men and horses, there can be no question that this attack had come as a complete surprise. One troop had been completely annihilated in march formation with scarcely a carbine discharged.

The white survivors of this initial assault had formed hasty lines of battle on the top of the ridge opposite the Indian camp. The arrangement of the defense had not been the best in the world but there had been no time to seek perfection. It would have made little difference. It had all been over in so incredibly short time. There were some carbines here, too that had not been fired often. Sometimes this was because the trooper didn't live very long. But many other times it was because the brass in the cartridge made by grafting commercial firms, was of such poor quality that the ejector tore through the lip without removing the spent case. When this happened the soldier had to punch the case out with his ramrod. This slowed his rate of fire which was slow enough at best because these were only single-shot weapons. The Indians, on the other hand, were armed with the most modern Remington repeating rifles which they had obtained in great numbers in exchange for fur and hides at the trading posts of the American fur companies. That it was a criminal offense to sell, barter or give a firearm to an Indian was no deterrent to these great American merchants.

How shall we evaluate Custer's actions on June 25, 1876, and how shall we account for them? Neither is possible with complete accuracy but both the evaluation and the explanation of his actions have been subjects of much speculation and many controversies.

As to judgment of his actions, hindsight is always more accurate than foresight. Monday morning quarterbacks are always successful. How much did Custer know when he made his plan of attack? This cannot be answered categorically. Custer was not on social speaking terms with many of his officers, and especially was not with Reno and Benteen who left the main body before Custer discussed its employment—if indeed, he ever discussed it with any of his officers. None in the five troops, that went with him to their doom, had the opportunity of recording any of his further orders. But there is ample evidence that his knowledge of the strength of the Indians was either false or entirely lacking—probably the latter. It is certain that he knew nothing of Crook's defeat.

And no one with any knowledge of the terrain across the river from the Indian camp would have selected that area as the place from which to launch an attack. So it is safe to say that Custer knew very little about the situation when he ordered the attack.

This leads only to the conclusion that his action was unsound to the point of recklessness. This was no insignificant campaign against a small band of hostile Indians. The very size of the Army forces indicated that this was generally realized. Terry's instructions urged caution and joint action by the several commands.

Why then did Custer pursue this course of action? His defense of his abandonment of parts of his command in previous fights had been that the safety of the bulk of his command demanded such action. Why on this occasion did he risk the safety of his command by precipitate action by attacking in broad daylight at the sacrifice of the important element of surprise by launching the attack with woefully inadequate information? This, too, is anyone's guess, but motivation by an overwhelming desire to re-establish a reputation that had been sadly damaged by unwise exploits seems to me to be the most satisfactory explanation.

It is a curious chain of events that led to Custer's first difficulties with higher authority which engendered such bitter resentment on his part. How much this resentment governed his future actions may be in the field of pure speculation, but there is evidence that it did exert a considerable influence. A few cholera vibrios slipped away from Europe with political refugees fleeing persecution. No sooner had their descendants arrived in America than they created havoc along thousands of miles of waterways and other highways of travel. Then, after having retired into obscurity for several years, succeeding generations again migrated hidden among artisans who were to build an outpost of civilization in the western wilderness, there again to emerge long enough to cause a minor disaster. Finally after twelve more years of inactivity they crept out once more from hiding to create in 1867, a situation which exerted a profound influence upon the life and career of George Armstrong Custer.

These generations of microbes traveled thousands of miles. They struck down hundreds of people, but the ultimate tragedy of their making it seems to me, happened in the valley of the Little Big Horn River almost three decades after they first came ashore in New Orleans.

A PSYCHIATRIST LOOKS AT CUSTER

KARL MENNINGER, M.D. Topeka, Kansas

DR. HAWLEY has asked me as a psychiatrist to make some comments upon the psychiatric implications of his fascinating account. We are given a portion of the case history of a cavalry officer of about 45 who was killed in action. We have the following pertinent data. He was a man

1. Who stood 34th in his class at West Point.
2. Who was made a Major General at the age of 25.
3. Who achieved a certain amount of military distinction in the service of the Union Army where his actions were characterized by aggressiveness.

4. Who was noted for his ostentatious dressing and bad manners. (See J. C. Haskell and other references cited by Douglas Southall Freeman in *Lee's Lieutenants* New York, Charles Scribner & Sons, 944 pages 734 ff.)

5. Who at the moment of supreme victory (Appomattox, April 9, 1865) violated military etiquette in many ways, loudly demanding surrender from his defeated and inactive enemy (General Longstreet) while General Lee and General Grant were conferring. (Op. cit.)

6. Who "took care of" and refused to return 120,000 pairs of spurs given by General Santa Anna to the father of one of his friends. (Op. cit.)

7. Who in the name of warfare ordered and executed surprise attacks upon communities of men, women and children and slaughtered the women and children along with the men.

8. Who took his own wife with him to a frontier assignment and later became so worried about her that he was impelled to forget or neglect his military duties.

9. Who deprived wounded soldiers under his own command of medical and surgical attention.

10. Who disregarded the safety and welfare of his troops to the extent of sending them into hostile territory with insufficient military preparation and protection to their almost certain (and quite pointless) death.

11. Who was convicted of one desertion of his own troops and was suspected of others.

12. Who either committed perjury or at least gave incorrect damaging testimony in court to satisfy personal spite.

13. Who disobeyed specific orders given by the one friend he seems to have retained and the one General that favored him in his behalf.

14. Who presumably planned the sacrifice of the lives of

From Winter Veterans Administration Hospital Topeka, Kansas

the bulk of his command in order to attempt to achieve minor pieces of personal military glory.

These data describe a personality type only too familiar to psychiatrists, falling into a category of psychopathology typically characterized by excessive vanity, complete disregard for the feelings or safety of others, a lack of loyalty either to cause or to friends, either to the principles of humanity or to the established code of ethics, and a conspicuousness of achievement at times passing for success under circumstances where ruthlessness and boldness are to some advantage.

When this type of personality was encountered among the enlisted men in World War II, it was very apt to come rather promptly to the attention of the psychiatrists and such individuals were "boarded out" on Section VIII or the equivalent. But when a man wears stars on his shoulders, he can "get away with" things for which he would be court-martialed or hospitalized were he a private. This is not to imply that this happened often, but every time it happened it destroyed the morale, if not the lives, of thousands of men committed to the charge of such incompetent leaders.

Three corollary questions come to my mind.

First of all, what is to be said of the act of General Terry—a man whose name and reputation are completely unknown to me—who in spite of Custer's bad record, in spite of the court-martial, in spite of bad behavior in connection with the trial of the Secretary of War and in spite of General Grant's express wishes, insisted on giving a position of leadership and responsibility to a man like Custer?

In the second place, why does the name of Custer still stand in the mind of the average American as that of a great hero?

And thirdly—if by some accident of fate Custer had been successful in his disobedient and ill-planned attempt at coup, what would have been the verdict of history?

REVIEWS OF NEW BOOKS

SINCE the text *La chirurgie en obstétrique* has been prepared for the use of the medical students at the University of Strasbourg, France, it is not particularly detailed in its presentation of the various subjects but strives instead to enunciate principles of surgery as applied to common surgical conditions occurring in obstetrics. The line drawings prepared by the senior author Dr Keller aid greatly in the elucidation of the text.

Surgical treatment of genital abnormalities such as imperforate hymen, acquired sterility due to pelvic inflammatory disease, ectopic pregnancy, various types of phlebitis, stenosis of the uterus and genital prolapse are a few of the topics discussed. The subjects of immediate repair of perineal tears and of episiotomy are not presented. In view of the audience toward whom this text is directed this omission would seem to be a definite oversight. A short discussion of genital prolapse is well done.

Many subjects are definitely brought up to date. Ligation of the vena cava of the utero-ovarian plexus, of the internal iliac and of the common iliac are all mentioned under pelvic thrombophlebitis. Low cervical cesarean section is popular in Strasbourg and is fully discussed. It is given a prominent place in the treatment of placenta previa and of cephalopelvic disproportion.

A plea is made in the preface for unified combined departments of obstetrics and gynecology for teaching, scientific research and clinical work. Strasbourg, and Tarnier are the only such in France. It is stated that those having combined interests are the most observant and the most scientifically productive. Mention is made of the 1931 French Surgical Congress at Paris on Low Cervical Cesarean Section at which Schickel and Brindeau dethroned the classical section and it is further stated that such capacity and understanding presupposes a surgical education preliminary to obstetrical gynecological specialization. With such training behind him as Couvelaire says, — "He will not tremble when he holds the scalpel."

VICTOR LIEFOWITZ.

MANY unrelated conditions from various fields of surgery are discussed in *Grandes problemas de clinica quirurgica*. Representative chapters include those on acute appendicitis, hyperthyroidism, cancer of the rectum, fracture of the wrist, gastric cancer, Buerger's disease, injuries of the testis, femur fracture, and diabetic gangrene. In all these and duodenal ulcer each devoted to a case and a thirty-one sections each devoted to a case presentation followed by a comprehensive discussion of all phases of the problem involved. There is a

LA CIRURGIA EN OBSTETRICIA. By R. Keller and A. Glatigny. Paris: Masson et Cie, Editeurs, 1936.
GRANDES PROBLEMAS DE CLINICA QUIRURGICA. By Dr Alfredo Velasco E. Santiago, Chile. Central de Publicaciones, 1945.

larger section on infection presenting the newer knowledge of the mechanisms of infection and immunity as well as the diagnosis and treatment of infection.

The discussions are interesting with emphasis clearly placed on the important points and the material is well organized from a didactic standpoint. The case presentations are careful and complete. There is little that is original and the volume will be of value chiefly for the teaching of fundamentals.

AURA P. DUCK.

THE small monograph of 208 pages entitled *Introduction to Surgery* by Frantz and Harvey presents in a clear concise manner the fundamental principles of surgery. There are six well arranged sections so grouped that the student may learn and quickly review the essentials he must know.

The instructor of surgery will find the book most helpful if he insists that his students understand its contents. By so doing he can be assured that they have the background necessary to absorb whatever surgical subject he may teach.

As it is true that those who work in surgery should have an understanding of medicine, so too medical men could profit well by reading this book of surgical principles. The authors are to be congratulated upon their excellent and helpful contribution.

RUSSELL T. BOTHE.

THE text on gynecological diagnosis by Professor Neuweiler of Bern combines painstaking thoroughness with strict observance of the limitations imposed by his title. In the first section he describes the proper method of taking the history and carrying out both general and special types of examination. There are excellent illustrations, particularly those of uteroculpingography in a variety of pathological states.

The remainder of the book is devoted to the diagnosis and differential diagnosis of gynecological cases under headings subdivided according to their anatomical location. Descriptions are accurate and complete and illustrations are abundant.

The text presents the subject almost exclusively from an anatomical point of view. Endocrinological and chemical diagnostic methods are not discussed nor is functional gynecological disease. The volume should be helpful not only to the student learning practical gynecological diagnosis, but also to the practitioner confronted with the occasional diagnostic problem.

PRELIMINARY PROGRAM FOR 1947 CLINICAL CONGRESS NEW YORK SEPTEMBER 8 TO 12 1947

THE thirty third Clinical Congress of the American College of Surgeons will be held in New York at The Waldorf Astoria from September 8 to 12. Planning of the program is being resumed at the point at which it was discontinued last year when the New York meeting had to be postponed because of the arrangements for the United Nations Assembly. The plans made previously will be carried out for the official meetings, operative and nonoperative clinics, panel discussions, symposia, forums, medical motion picture showings, and technical and scientific exhibits. The twenty sixth annual Hospital Standardization Conference will also be held as part of the Clinical Congress, with a four-day program of panel discussions, symposia, and round table conferences.

SIXTH NEW YORK CONGRESS

This will be the sixth time that the Clinical Congress has been held in New York. The first time was in 1912 when the old Waldorf Astoria was the scene of the third Congress. Dr. George E. Brewer was the Chairman and Dr. Charles H. Peck the Secretary of the 1912 Committee on Arrangements. Dr. Edward Martin of Philadelphia was then President of the Clinical Congress of Surgeons of North America. More than 2,600 physicians registered and the lack of organization for regulating the attendance at the clinics precipitated the proposal by Dr. Franklin H. Martin

at the business meeting on November 15 for the creation of the College. Later Congresses were held in New York in 1919, 1924, 1931 and 1938.

CLINICAL PROGRAM

The hospitals and medical schools of Greater New York are co-operating in scheduling operative and nonoperative clinics. The program that they prepared last year under the guidance of the local Committee on Arrangements, when there was prospect of holding the Congress in New York, is substantially the same as that planned for this year with such revisions as seem desirable in view of scientific developments and changes in personnel. The preliminary program was published in the August, 1946 issue of SURGERY GYNECOLOGY AND OBSTETRICS, pages 275 to 288.

Visiting surgeons will have ample opportunity to attend well arranged programs of many different kinds in a number of the excellent hospitals in the New York metropolitan area. General and special demonstrations will be held on subjects such as fractures, cancer, maternal morbidity and end result studies, newer diagnostic and therapeutic procedures, preoperative and postoperative supportive treatment, anesthesia and reconditioning. Clinicopathologic and x-ray conferences will also be held. The newer techniques and surgical procedures may be observed.

The medical schools will hold a series of exhibits demonstrating their work which will be on

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

1015

display in their affiliated hospitals. The program of each hospital will be arranged to cover subjects in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery and ophthalmology and otolaryngology.

PRESIDENTIAL MEETING

On Monday evening in the Grand Ballroom the Presidential Meeting will be opened with the impressive processional of the officers, Regents and honorary guests. Welcome to the assembly will be extended by the Chairman of the Committee on Arrangements, Dr. Howard A. Patterson. Dr. Irvin Abell of Louisville, President of the College, will preside and will deliver the Presidential Address. An inaugural ceremony will be held for the incoming officers. Foreign guests will then be introduced.

The second Martin Memorial Lecture will be delivered. This lectureship was established upon motion of the Board of Regents at its midyear meeting on April 1, 1946 as a memorial to both Dr. Franklin H. Martin and Mrs. Martin. The founder of the College and of SURGERY, GYNECOLOGY AND OBSTETRICS was joined by his wife in making the College the beneficiary at their deaths of the Journal together with its physical plant operated by The Surgical Publishing Company of Chicago of which they were the owners. Doctor Martin died in 1935 and Mrs. Martin in 1945. The Martin Memorial Lecture is to be given annually during the Clinical Congress. It will deal with a scientific subject of the author's own choosing. It supplants the former Annual Oratorion in Surgery.

CONVOCATION

The Convocation is scheduled for Friday evening, the plan of separating it from the Presidential Meeting having proved to be quite successful. At the 1946 Clinical Congress in Cleveland an Assembly of Initiates will be held prior to the Convocation on Friday in order to instruct them in the Convocation procedure and other matters.

The Convocation will open with a processional of officers, Regents, and Governors. The new President, Dr. Arthur W. Allen, will preside and will make the opening remarks, confer the honorary fellowships, and present the candidates for fellowship. Following this ceremony the Fellow ship Address will be given.

SCIENTIFIC SESSIONS

The scientific sessions, to be held on Tuesday, Wednesday and Thursday evenings, will be ad-

dressd by eminent surgeons and specialists recognized as authorities in their fields. Special scientific meetings will be arranged on the same evenings for specialists in ophthalmology and otolaryngology. The newest developments in general and special fields will be presented in the well rounded program.

Every afternoon, from Monday through Thursday, panel discussions led by recognized authorities in each field, aided by well qualified collaborators, will be held. Similar meetings held during past Congresses have been most successful largely because they permit the participation of a large number of surgeons, thus increasing the opportunities to learn from the experiences of others.

Preliminary plans include the holding on one afternoon of a symposium on fractures and other traumas, and a symposium on cancer on another afternoon. There is always wide interest in these special meetings. Plans for several new features have been discussed but cannot be announced until definite decisions have been made in cooperation with the Committee on Arrangements.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday and Friday mornings. Included will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned, but questions and comments will be invited. Dr. Owen H. Wangensteen of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the Forum, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

HOSPITAL STANDARDIZATION CONFERENCE

The first formal session of the Clinical Congress will be the opening meeting of the twenty eighth Hospital Standardization Conference. Dr. Irvin Abell of Louisville, President of the College, will preside. The hospital conferences will continue on Monday afternoon with sessions following on Tuesday, Wednesday and Thursday mornings, afternoons, and evenings.

Hospital administrators, members of governing boards, heads of the various hospital departments

and their personnel, nursing groups, and many other persons directly or indirectly concerned about hospital progress will be interested in the discussion of current hospital problems. National organizations representing various groups of hospital personnel will co-operate and participate in the meetings, which will include formal sessions, panel discussions, round table conferences, and open forums.

ADVANCE REGISTRATION

The hospitals and medical schools of New York afford accommodations for a large number of visiting surgeons. However in order to insure against overcrowding attendance at the Congress will be limited to the number that can be comfortably accommodated at the meetings and also by accommodations in the hotels. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

The members of the Board of Regents regret that conditions beyond their control will not permit unpaid registration at the 1947 Clinical Congress. They voted to restore the registration fee of \$5.00 for Fellows and for endorsed Junior Candidates. Non-Fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates of the class of 1947.

To each surgeon who registers in advance a formal receipt will be issued. This is to be exchanged for a general admission card upon his registration at headquarters during the Congress. This card is not transferable and must be presented in order to obtain clinic tickets and admission to scientific sessions.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be located in the Basiloon Room, Jade Room, and Astor Gallery all on the third floor of the hotel. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals, and publishers of medical books will be represented in the exhibition.

HOTEL RESERVATIONS

Although the prospect is that the hotel situation in New York will be more favorable than it would have been last year nevertheless there is still a critical shortage of hotel rooms and early reservations are most desirable. In making these, it is urged that communications be addressed to the New York Convention Bureau, through which all reservations for the Clinical Congress are to

clear. No correspondence should be sent directly to the hotels. A letter will be received by all Fellows in which the procedure will be outlined, with which will be enclosed a form to be used in making reservations. First, second, third fourth, and fifth choices of hotels may be designated. The following hotels are recommended by the Committee

	Maximum rates with bath	
	Single	Double
Alberton House, 143 East 59th Street	\$ 75	\$
Alberton House for Women, 130 East 57th Street.	3 00	
Ambassador, Park Avenue and 51st Street	6 00	
Astor Broadway and 44th Street	3 50	4 00
Barbizon (Women) Lexington Avenue and 63rd Street.	3 50

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday

- 9:30 General Assembly for Surgeons and Hospital Representatives, Grand Ballroom
- 1:30-3:00 Panel Discussion, Empire Room
- 2:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 2:00 Hospital Conference, Sert Room
- 2:00 Surgical Film Exhibition (General), Grand Ballroom
- 3:30-5:00 Panel Discussion, Empire Room
- 8:15 Presidential Meeting, Grand Ballroom

Tuesday

- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Jensen Suite
- 10:00 Surgical Film Exhibition (General), Empire Room
- 10:00 Panel Discussions
- 11:00 Panel Discussion—Otorhinolaryngology
- 1:30-3:00 Panel Discussion, Grand Ballroom
- 2:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 2:00 Hospital Conference, Sert Room
- 2:00 Symposium on Fractures and Other Traumas
- 2:00 Surgical Film Exhibition (General), Empire Room
- 3:30-5:00 Panel Discussion, Grand Ballroom
- 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
- 7:30 Hospital Conference—Trustees, Sert Room
- 8:00 Scientific Session, General Surgery, Grand Ballroom
- 8:00 Scientific Session, Ophthalmology, Jensen Suite
- 8:00 Scientific Session, Otorhinolaryngology, Le Perroquet Suite

Wednesday

- 8:00 Meeting of Cancer Committee, Carpenter Foyer and Dining Room
- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
- 10:00 Surgical Film Exhibition (General), Empire Room
- 9:30 Executive Committees
- 10:15 Credentials Committees and Committees on Applicants
- 11:00 Judiciary Committees
- 11:00 Panel Discussions
- 11:00 Otorhinolaryngology
- 12:00 Meeting of Board of Governors, Jensen Suite
- 1:30-3:00 Panel Discussion, Grand Ballroom
- 2:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 2:00 Symposium on Cancer, Empire Room
- 2:00 Surgical Film Exhibition (General), Empire Room

- 2:00 Hospital Conference, Sert Room
- 3:30-5:00 Panel Discussion, Grand Ballroom
- 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
- 7:30 Hospital Conference, Sert Room
- 8:00 Scientific Session, General Surgery, Grand Ballroom
- 8:00 Scientific Session (Eye, Ear, Nose and Throat), Empire Room

Thursday

- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
- 10:00 Surgical Film Exhibition (General), Empire Room
- 11:00 Panel Discussions
- 11:00 Ophthalmology
- 1:30 Adjourned Meeting, Governors, Grand Ballroom
- 1:45 Annual Meeting, Fellows, Grand Ballroom
- 2:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 2:00 Hospital Conference, Sert Room
- 3:00 Panel Discussion—Graduate Training in Surgery, Jensen Suite
- 3:30-5:00 Panel Discussion, Grand Ballroom
- 3:30 Surgical Film Exhibition (General), Empire Room
- 3:30 National and Regional Fracture Committee, Le Perroquet Suite
- 4:00 Committee on the Library, Room 4 J
- 4:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
- 7:00 Surgical Film Exhibition, Grand Ballroom
- 8:00 Scientific Session, General Surgery, Grand Ballroom
- 8:00 Scientific Session, Ophthalmology, Empire Room
- 8:00 Scientific Session, Otorhinolaryngology, Sert Room

Friday

- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
- 10:00 Surgical Film Exhibition (General), Empire Room
- 1:30 Assembly of Initiates, Grand Ballroom
- 1:30 Panel Discussion, General Surgery
- 2:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 2:00 Panel Discussions
- 2:00-4:00 Panel Discussion, Sert Room
- Obstetrics, Sert Room
- Plastic Surgery, 4 U Blue Room
- Neurological Surgery, Assembly Room M N
- Thoracic Surgery, Jensen Suite
- Urology, Le Perroquet Suite
- Orthopedic Surgery, Carpenter Foyer and Dining Room
- 2:00 Surgical Film Exhibition (General), Empire Room
- 3:30 Panel Discussion, General Surgery
- 8:15 Convocation, Grand Ballroom

BOARD OF REGENTS OF AMERICAN COLLEGE OF SURGEONS CONSIDERS DELAYS IN APPOINTMENTS TO HOSPITAL STAFFS

COMPLAINTS having come from several sources about difficulties being placed in the way of returning medical veterans who were applying for hospital privileges, the Board of Regents of the American College of Surgeons at a meeting in Hot Springs, Virginia, on April 24 carefully considered the problem of helping veterans and other younger surgeons in obtaining appointments. Several specific cases of seemingly unjustifiable delay were studied, together with such contributory hospital conditions as the existing shortage of beds and long waiting lists of patients. The result of the deliberation was the presentation and adoption by the Board of Regents of the following resolution

WHEREAS it has come to the attention of the American College of Surgeons that many well trained surgeons, especially returned veterans, who have located or have signified their intention of locating in communities where there are hospital facilities have been denied hospital privileges until they had been in residence in that locality for six months to a year

Be It RESOLVED that the Board of Regents of the American College of Surgeons disapproves of the practice and although fully cognizant of the shortage of hospital beds, the Board believes that such well trained competent, and ethical individuals should be given similar opportunities as offered established medical practitioners of the community

COLLECTIVE REVIEW

THE TREATMENT OF INJURIES OF THE SPINAL CORD

JOHN MARTIN M.D. F.A.C.S. Chicago, Illinois

DURING the decade just past there has been a mounting interest in the problem of the patient with traumatic paraplegia, and the literature has been swollen with the opinions of general surgeons, orthopedic surgeons, neurosurgeons, neurologists, pathologists, and physical therapists, as well as those interested in the complications of these injuries, such as the plastic surgeons and urologists. The record attained in the treatment of these patients in World War I is not a very enviable one, and it is quite apparent that the methods of treatment of traumatic paraplegia were not improved by the rich experience of that war. In the succeeding years the majority of the patients were injured in industrial or traffic accidents, and the greater part of the injuries were of the closed fracture-dislocation type. With the advent of World War II and its tremendous number of patients with injuries of the spinal cord from every conceivable cause, a second opportunity for improvement in methods of treatment was at hand. To judge from the number of reports alone, one must conclude that a renewed interest in the subject of traumatic paraplegia has arisen out of the earnest effort of the medical corps of the United States Army and Navy to meet the challenge of the care of these tragically injured patients. It is quite apparent, as might be expected, that all military care was not ideal; it is also apparent that the civilian standards of care have left and still do leave much to be desired. The present literature is not 100 per cent assuring, but the current general

methods of treatment are for the most part in accord; they are based on sound surgical principles and a knowledge of physiology and they have been matured by the recent experience of the war.

This review has to do with the subject of treatment only and is concerned only with those patients in whom the spinal cord or cauda equina was injured and not with spinal injuries alone. The literature from 1936 to 1940 is noteworthy for its paucity of new ideas or fresh statements. However with the war there came a deluge of reports, some good, many bad, but all with undeniable fervor. Many authors have made the mistake of prefacing an otherwise good paper with long and tedious accounts of the anatomy and physiology of the vertebral column and the spinal cord—an undertaking invariably better handled by the average text of anatomy. Over and over again the reader is forced to review the mechanism of the flexion injury to look at time-worn diagrams and reproductions of roentgenograms. One encounters hobbles which have been ridden until they are irritating. But the whole composite, taken, sifted, and digested, is bound to leave the reader with something new, appealing, useful, and hopeful.

One encounters at every turn in the expressions of all authors the same recurring questions. When shall decompressive laminectomy be done? What are the criteria for operation? How can the spinal deformity be best reduced, by the closed method such as the Taylor method, or by the traction methods with a chin halter or the Crutchfield tongs in the cervical injuries? Are casts ever to be used when there is severe neural injury? Of what prognostic value are the reflexes? What are the

From the Department of Surgery Northwestern University Medical School, Chicago, Illinois. A review of the literature from 1936 to 1946.

disasters resulting from the transportation of the injured patient, and how are they to be avoided? How long must the injured spine be immobilized in the various types of fractures? (Opinions vary from 6 weeks to 12 months) What is the best method for the care of the paralyzed bladder? How far should surgery go in the correction of spasticity, spasms, and pain? Is surgical repair of the cauda equina feasible? To judge from the lack of agreement between writers whose opinions must be respected, one would at first gain the impression that nothing new is gained, nothing old has been solved. Yet that is not the case. The treatment of the paraplegic patient has improved immeasurably during the past 10 years, and it is still improving.

THE EARLY PHASE OF TREATMENT

First aid transportation "The management of a patient who has a spinal injury should begin at the scene of trauma. (78) "Proper early care depends upon proper early diagnosis" (12) Those and many other authors (1 11 21 22 51 57 59 76 80 82 91 100 115) have stressed the importance of intelligent early treatment of the patient with an injury of the spinal cord. Well intentioned but bungling first aid workers, resuscitating squads, anxious relatives, policemen, and even bystanders at the scene of an accident may by their improper handling of the patient, add irreparable damage to an already injured spinal cord by their insistence on doing something for the injured person. As in any other serious injury, there is seldom great need for special haste in moving the patient, and care mixed with emotional stress is likely to result in further disaster. Palmer pointed out that any unconscious patient who may have received a spinal or spinal cord injury should be treated exactly as if he were known to have been so injured, until the actual extent of injury can be ascertained, and others, as Thomson, have warned against the danger of increasing the jackknife deformity by lifting the patient improperly or without sufficient help. The simple instruction stated by Davidoff that the first point of emergency treatment is to leave the patient flat on the ground, right where he originally lay until proper help and means of transportation are available, is perhaps the most important and altogether sane procedure that can be advised, for Davidoff, as the others, is most concerned with the additional trauma that can be caused by loosened vertebrae and bone fragments when the patient is moved. It is stressed by many who have had the early care of such patients that at least 3 and preferably 4, persons are required to

lift the patient with an injured spine, and if there is injury to the cervical spine or cord, an extra person is needed to hold the head in a fixed, slightly extended position throughout all the maneuvers of moving.

Many patients with recent fracture of the spine, with or without cord injury, suffer severe root pains at the segment of injury. Authors are disagreed upon the subject of administration of morphine to relieve the pain. Coleman and Pilcher (78) state "Morphine sulphate should be given without hesitation in dosage (0.016 gm. or $\frac{1}{4}$ gr.) sufficient to bring relief of this pain" Knight, McAlpine, and others agree to such medication. Others, however, as Wortis and Sharp, made special admonition against such medication, and Davis (22) stated "Morphine should not be given to patients with injuries to the cervical spinal column. It would seem best, everything considered, to avoid morphine if other measures to allay the pain can be found, for certainly patients with injuries to the cervical cord, especially may already have respiratory difficulties which would only be increased by morphine in sufficient dosage to stop the pain, and, furthermore, such medication may mask other important neurological signs. Root pains are most likely to occur in cervical spine injuries; fortunately, this is the portion of the spine most easily handled by traction, and it is the usual thing to see a patient immediately relieved of his root pain as soon as adequate traction is applied to pull the involved vertebrae apart.

The subject of the position of the patient while in transit from scene of accident to the hospital has been a matter of detailed description as well as of disagreement among many surgeons. Why there should be disagreement is a strange thing, since it would seem obvious, (as it has to many experienced men) that the preservation of the anatomical position, with fixation and immobilization by temporary means at the level of injury is the all important consideration. Thomson was so concerned that the jackknife deformity be not further increased that he advised the transportation of all patients with spinal injuries in the prone position apparently even advising this for cervical injuries. Platt, on the other hand, believed that patients with cervical injuries should be transported in the supine position, with the neck immobilized but that in all other spinal injuries the patient should be transported prone, except that when there are chest injuries or when the fracture is a lower lumbar one the patient should lie face up with proper support under the lumbar curve. McAlpine advised the prone position for lumbar injuries and the supine position for cervical in-

jures, in either case immobilizing the spine at the level of injury and adding extra support to maintain the normal points of curvature. Knight recommends the prone position either on a blanket or stretcher, to maintain hyperextension of all parts of the spine. Other authorities (76-100) recommend the supine position for all methods of transportation. The majority of neurological surgeons insist upon the supine position, on a rigid surface. Such a position allows satisfactory examination does not interfere with the treatment of chest or abdominal complications permits the maximal respiratory excursion for the patient, and, with the cervical and lumbar spine supported with a roll of clothing or blanket, keeps the proper position of moderate hyperextension. Davis (22) states the problem tersely and is here quoted:

"The most important principle in the emergency treatment of fracture-dislocations of the spine is to do nothing which will increase the bony deformity. The patient should not be moved unless it is absolutely necessary because each new movement may cause bony fragments to cut into the spinal cord. The patient's head should not be raised to give him a drink or cigarette. A rolled blanket or pillow should not be placed beneath the head. He should not be lifted off the ground unless he is on a litter or other rigid support. Reduction should not be attempted. Plaster casts should not be applied. The patient with a fracture dislocation of the cervical spine is in the optimal position when he is lying on his back with a folded blanket 3 to 4 inches thick beneath his shoulders, with his head below the level of his shoulders and his neck in slight dorsiflexion (hyperextension). Folded blankets should be secured at both sides of the head to prevent lateral movement. He should not be face down with his neck twisted nor upon his side with his neck flexed laterally. Care should be taken that clothing and blankets are smooth beneath the patient. Pockets should be emptied. Three persons are needed to turn properly a patient with a fracture dislocation of the neck onto his back from some less favorable position. One should grasp the chin and occiput and exert steady traction in the line of the long axis of the body. The second should grasp the ankles and exert equal countertraction along the same line of pull. The third should then kneel beside the patient, reach across his body and grasp the patient's clothing near the shoulder and near the hip joint with his two hands. He should then gently rotate the patient toward himself while the men at the head and feet exert their traction. The head, neck, body and legs should

be so placed on the ground or the litter that the patient's shoulders finally come to rest on top of it when rotation has been completed. This position will allow the head to hang down slightly and permit a moderate dorsiflexion (hyperextension) of the cervical spine, a position which tends to correct the deformity caused by the fracture-dislocation. If the patient is lying face upward on the ground the 3 men should take the same position as for turning him, with the exception that the man at the side should grasp the patient's clothing on the side nearest to himself. The 3 men should then gently slide the patient from the ground onto the litter without lifting him. The 2 men at the head and feet should meanwhile maintain a strong longitudinal traction. The fundamental principles for the emergency treatment of compression fractures of the lumbar spine are essentially the same as for fractures of the cervical spine; the patient should not be moved unless it is absolutely necessary. He should not be picked up and carried from one place to another unless he has first been placed upon a litter or other rigid structure. There are two acceptable positions for a patient with a compression fracture of the body or one of the lumbar vertebrae. If an air mattress is available, the patient should be placed upon it, lying upon his back, with 2 or 3 folded blankets underneath the air mattress at the site of the fracture so placed as to produce hyperextension of the spine. If an air mattress is not available, then the best position is the face-down position. This position automatically prevents further anterior flexion of the lumbar spine. No other attempts at correction of the bony deformity should be made. The principles involved in turning a patient with a compression fracture of the lumbar spine are similar to those for turning a patient with a fractured cervical spine except that in fractures of the lumbar spine traction by the man at the head of the patient may be applied under the armpits. In transferring the patient from the ground to the stretcher the same principles apply as in the case of a patient with a fracture-dislocation of the neck.

Munro (70) advised the face-down position for the transportation of the patient with an injury of the cervical spine, and he agreed with most others that at no time should manual reduction of the injury be done at the site of the accident. Clark advised the earliest possible manual reduction of fracture-dislocations of the cervical spine at the scene of the accident, since he feared the ill effects of transportation on the unreduced spine and the adjacent injured cord. This is the one instance in which such early reduction is advised. Raaf has

found useful the immediate application of the Schreiber pneumatic collar before the patient with a cervical injury is started on his way to the hospital.

Spinal shock This term has been rolled about loosely frequently to the confusion of the reader. Certainly any patient with an injury of the spinal cord, with or without concurrent injury of other parts of the body may suffer from shock as it is usually known with a fall in blood pressure, a low body temperature, a poor pulse, and evidence of poor peripheral circulation. Obviously the usual supportive measures for such a condition must be instituted before any form of active treatment can be begun. Kennedy decried the use of the term, calling it inaccurate and unjustified, and pointed out that early in the phase of spinal cord injury (during spinal shock?) nothing will prove the differentiation between a complete anatomical and complete physiological lesion other than direct inspection. Spinal shock is usually taken to mean that period following injury when the patient is completely flaccid and without reflex response of any type below the upper level of his injury and when cord function is completely lacking. Elsberg has stated that plantar flexion of the great toes is usually the only reflex movement that can be elicited upon scratching the sole of the foot during the first few weeks after complete transverse lesion of the spinal cord, and that the appearance of the Babinski sign within the first 3 weeks after injury is evidence of the incompleteness of the lesion. However the appearance of reflexes, either flexor or extensor does not necessarily always coincide with the change from flaccidity to spasticity and many authors would prefer to apply the term "spinal shock" for whatever indications it might have (and they are probably few) relative to surgical care, to that period of the first 2 to 4 days after injury when the patient is completely flaccid and without any response of any sort below the level of the lesion. At best, the term does not seem a very useful one for its indications as to care or prognosis. Kennedy believed that it is absurd and should be discarded.

THE PHASE OF ACTIVE TREATMENT

Clinical examination the Queckenstedt test x-ray examination. There is general agreement that the earlier the patient is examined and the extent of his injuries determined, the better it is for all concerned. Neurological surgeons and neurologists are interested primarily in the nature and extent of the neural injury; general and orthopedic surgeons are usually concerned with the bony deformity and the problem of its correction. Some

of either group are capable of combining these interests in the proper proportion. Davis (31 32) Coleman and Pilcher (78) Oldberg and other neurological surgeons insist upon the early neurological examination of the patient, without undue manipulation of his body and point out that such examination must be recorded so that subsequent examinations can be compared with the first findings. Spinal puncture with performance of the Queckenstedt test to determine the presence or absence of a block of the spinal fluid is usually done when the cord injury is attended by obvious spinal deformity whether the surgeon is opposed to operative treatment or not. Davidoff, Davis (21 32) Stuck (109, 110), Worts and Sharp, and others believe that a positive Queckenstedt test, along with other findings, may be one of the criteria for laminectomy but apparently no author believes that the presence of a block alone is sufficient cause for open operation when there is evidence of complete loss of cord function. Worts and Sharp state that "spinal tap should be performed and, if manometric block is present and the clinical signs increase (in the case of the incomplete cord lesion) decompressive laminectomy is indicated. This group is the only one in which spinal fluid manometric studies are of value. We do not believe that routine spinal taps in all cases of acute fracture of the spine are necessary. Only those patients should have lumbar puncture manometric tests who, it is believed, can be helped by operation.

The procedure has definite risk associated in the act of moving the patient." Pilcher believed, also, that when the lesion was apparently incomplete, a positive Queckenstedt test together with x ray evidence of compression constituted an indication for laminectomy. Mayfield and Cazan do not put much dependence in the Queckenstedt test, nor do they believe when it is positive that it is a good indication for laminectomy. It is not infallible because, as Poppen and Huxthal showed, the response to jugular compression will be normal so long as the lumen of the subarachnoidal space is not less than the bore of the needle. Therefore, severe pressure may be present on the cord and still not show a complete block. "We would consider laminectomy indicated in compression injuries of the cord only if there was an incomplete lesion and the patient were showing progressive loss of function, and the loss of function could not be arrested by closed manipulation (58).

It is no surprise or secret that even the best of x-ray pictures of the injured spine may by no means show all the injury present, or the presence of such important factors as spicules of bone which

have been driven upon or into the cord. While it is the general consensus that careful and early roentgenological study of the injured spine is in order in every case of spinal cord injury no author has stated that evidence of bony damage by such examination constitutes alone an indication for open operation. It may, however, be an accurate guide to methods of closed reduction of the spinal injury. Kennedy noted that x rays of the spine are by no means conclusive of fracture of the laminae or the spines and quoted Browder and Miner as follows "Negative x ray findings do not necessarily exclude the possibility of a bone lesion." Jefferson (44) made the important observation that flat plates were not sufficient when the injured spine is x rayed, stereoscopic anteroposterior views should always be taken. Portable or other bedside films are usually of such poor quality that they will give only an approximate estimation of the bone injury although they have been found useful by all surgeons when the views are taken in a lateral position in cervical injuries to determine quickly and with little movement of the patient the presence and extent of a cervical fracture-dislocation. They are useful too after methods of closed reduction have been applied, to follow the course of the patient from day to day as he remains in position in his bed. However if operative indications depend heavily upon the extent and nature of the bone injury then the pictures should be carefully studied by means of x rays on the regular x ray table fitted with a Buckey apparatus and the pictures should be taken with as little movement as possible. Usually such films are made while the patient is on his way to the operating room so that little additional movement is necessitated in obtaining these pictures.

Closed reduction and conservative care as laminesctomy. With but very few exceptions most surgeons agree that treatment of the patient with a spinal cord injury should be delayed until he is out of his primary shock and in condition for whatever treatment may be necessary. Until that time he is given supportive care and maintained immobile without any attempt to correct the spine from its position when the patient was first found injured. All spinal injuries with or without cord injury should be corrected if possible. Packard stated All fractures with deformity should be corrected whether cord injury is present or not. If cord injury is present correction reduces pressure. If cord injury is not present, deformity is still undesirable as it produces a faulty weight-bearing line, chronic pain and disability. As Ruth pointed out, hyperextension is not a cure-all for

injuries of the spine. Emergency and therefore sometimes hysterical, attempts at hyperextension of the freshly injured back may do as much damage as flexion would do. In accord with the nature of the injury hyperextension may force backward upon the cord a displaced articular facet or fractured lamina and add an injury which did not originally exist. Ruth believed that there is a tendency in injuries of the spine for the parts to assume normal relationships and that maximum distortion occurs at the instant of the impact, the parts thereafter immediately springing back until their return is checked by abnormal bony impingement. Therefore x-ray examination rarely shows the maximum amount of displacement that occurred at the moment of injury, for it is, no doubt, at the very instant of impact and fullest distortion that the cord receives its maximum injury sometimes quite out of keeping with the later mild or absent signs of bone injury. For that reason Ruth believed that hyperextension should not be done until all means of full treatment are at hand and the exact nature of the bone change has been determined. Rather the spine should be stabilized in its original post traumatic state so far as early care is concerned.

Every author has his favorite method of effecting closed reduction. Johnson, along with many others (11 25 41 46 112) favors the Walton or Taylor method of closed manipulation for the reduction of spinal fractures, even in the cervical region, together with the use of such special apparatus as the Bradford frame, the Goldthwait frame, various types of hammocks and slings, and plaster immobilization. Jefferson (44) stated that he believed that to reduce cervical dislocations by such means was by no means a guarantee that the injury would stay in proper alignment, since the torn supporting ligaments frequently allow dislocation to recur. Morrison pointed out that while many cases the proper treatment, hyperextension is contraindicated (1) when there are obviously torn anterior vertebral ligaments, (2) when there are fractures of the elements of the posterior arches, and (3) when fractures associated with known cord damage will lead to open operation. Many writers have pointed out the danger of exerting hyperextension and applying a body jacket with a pad over the site of injury when the thoracic cord has been injured and fractures are present in the posterior spinal elements at the level of the lesion. By so doing they stated, the loose bone fragments may be forced down upon the exposed, swollen cord which is subject to further injury with but very little effort. Voris indi-

cated that manipulation with the patient under anesthesia probably gives a higher mortality than laminectomy and that it is a dangerous procedure in that further cord damage may result. Stuck (109-110) stated "Manipulation of the spine under an anesthetic, which has been advised for fractured vertebrae, is contraindicated because of the danger of further cord damage. He recognized that the early care of the patient may be entirely orthopedic in nature, but insisted that if the injury were cervical, the reduction should be accomplished by means of the Crutchfield tongs with the neck in hyperextension, whereas if the injury were thoracic or lumbar reduction should be accomplished by means of the proper cast or a hyperextension bed frame. Gallie apparently speaking from experience, stated "Efforts to reduce the dislocation by manipulation are attended by such appalling risk of damage to the spinal cord that they should not be employed. I saw one such disaster, and it was enough." Sammons saw no special value at any time in the operative treatment of compression fracture of the spine with a transverse lesion of the cord, but did believe that reduction by the closed method should be obtained early. He added, "Modern methods of reduction of fracture-dislocation have entirely supplanted laminectomy." That latter statement, however, is not fully in accord with the majority of neurological surgeons, when one considers all the factors which must be gone over in arriving at the decision to operate or not to operate.

Most authors agree that the final position of the patient with an injury to the thoracic or lumbar spine, with or without cord injury and whether or not subjected to laminectomy when the cord has been injured, should be that of hyperextension, with fixation either on a special hyperextension bed with a reverse spring mechanism or by means of rolled blankets under the mattress and without a plaster cast (the methods most often used by the neurological surgeons) or with fixation by means of a plaster cast sometimes extending as far as the knees (the methods employed by some orthopedic surgeons). Most surgeons agree that plaster casts make many problems of nursing care, contribute to the formation of bedsores and frequently add to the general discomfort of the patient but then apparently some surgeons regard these complications as the natural and expected outcome of spinal cord injuries, especially the development of bedsores.

Aside from the advocates of the closed manual method of reduction of cervical fracture dislocation, most authors are agreed that some form of skeletal traction is preferable in the care of these

seriously injured persons. Munro and Wegner (73) have used the Hoen method of putting piano wire under the calvarium at the vertex and attaching weights thereto but they found the method unsatisfactory and prefer to use simple halter chin-occiput traction with no more than about 5 pounds of weight however this must be used over a period of from 5 to 6 weeks. They apparently do not use the Crutchfield tongs. Sucha also tried the Hoen method and discarded it because of its dangers and complications he now uses the original clevis type of skull tongs. Peyton Hall and French described a method of inserting fish hooks under the zygomatic arches and applying traction, pointing out its simplicity of application and its effectiveness because the use of heavy weights was possible. However in the hands of most neurological surgeons, and apparently also in those of an increasing number of general and orthopedic surgeons, the use of the Crutchfield tongs (17) has proved the simplest, most effective, and safest method of treating fracture-dislocations of the cervical spine. It has been the common experience of all surgeons using this method that the application of the tongs is a minor procedure quickly carried out without manipulation of the patient weights up to 25 or 30 pounds can be applied for reduction of the more severe injuries, reduction is usually obtained early and the patient is immediately relieved of local and root pains upon application of the weights. This method allows the free movement of the patient's body for nursing care, does not interfere with his eating, and does not subject him to all the well known annoyances which halter traction (so much less efficient in the hands of most surgeons) causes the patient who must wear such a contraption. It has become standard practice to apply traction early in cases of fracture-dislocation of the cervical spine when there is no open wound and when there is no evidence of indriven bone spicules or other foreign bodies. The method was used extensively in the military hospitals during the war just past, and repeated accounts of its use and the enthusiasm of the surgeons will be found in the reports of cord injuries in the Army and Navy journals.

The great bone of contention however in the treatment of injuries of the spinal cord concerns the problem of when, if ever laminectomy is to be performed. Almost every reference furnished with this review will be found to voice the author's individual opinions regarding the wisdom of performing decompressive laminectomy. Browder and Grimes, Davidoff Davis (21-22) Elsberg, Fay Jefferson (44, 45), Kennedy Denker and Osborne, Love, Mayfield and Casan, Munro (65-

(13) Naffziger Coleman, Meredith and Pilcher (78, 13) Oldberg Pool, Rand Scarff (102) Spurling and Bradford, Stookey Voris, Wortis and Sharp and various medical authorities concerned with military medical problems (113) together with others experienced and well known in the field of neurological surgery and all well aware of the problems of the traumatic paraplegic patient, have clearly stated their stand and all with good logic. Yet, as will be seen later by comparison with the opinions of urologists on the care of the paralyzed bladder authorities disagree. The older neurosurgeons with a background of sound experience have as a group settled down to a not too-hopeful, most realistic, and not by any means colored with optimism attitude. Many of them have had experience with both the military and civilian types of injuries and therefore have dealt with both the open and closed types of injuries. The younger surgeons especially those who saw many patients with both types of injuries, but pre-dominately those with the open type during for-foreign service in the war just past have a much more hopeful and enthusiastic regard for the possibilities of early surgery. Perhaps their hope is based on insufficient experience but it is also possible, as indicated in a recent report by Tinsley that their hopes are well grounded and that their willingness to tackle the problem with unbiased enthusiasm will initiate a new attitude on the part of neurosurgeons in general. The older surgeons say in brief, "The damage is done why prolong the show?" The less pessimistic surgeons say "Nothing was ever gained by *laissez faire* give the patient the benefit of the doubt. Naffziger stated that with evidences of a complete lesion which persist for 24 hours after injury surgery is probably of no benefit and permanent paralysis is expected. He pointed out, however that the surgeon must not overlook the difference between the cervical and thoracic cord injury and injury to the cauda equina the last being of the peripheral nerve type and therefore much more amenable to surgical treatment. Rand among the older and more experienced group is more lenient toward operation although yet not misled by undue optimism. He stated "There is a certain psychological angle to be taken into consideration. Almost every patient with a broken back and paralyzed legs comes to feel sooner or later that he should have an operation. Therefore even though it offers very little, laminectomy may be carried out in order that he may feel that nothing has been overlooked. I have often felt that if I had broken my back and become paraplegic, I would prefer that the spinal cord should be explored. The same

question recurs every time I see one of these unfortunate individuals. Cases are on record in which patients with a complete transverse lesion of the cord persisting more than 24 hours before surgery have regained partial recovery after surgical decompression when block and compression existed, although the opinion has been stated by Naffziger and others that damage is *damage irre- vocable* in the spinal cord, and that any recovery that comes about after surgery would most likely have appeared eventually even without the operation. Certainly decompressive laminectomy weeks and months after injury rarely offers any benefit when evidence of a complete transverse lesion has persisted. This is not true, according to various case reports, even in the late operations when the lesion has been incomplete and not progressive. Early or late, operation has much more to offer in injuries of the cauda equina than it does in injuries of the spinal cord. Even those who advocate routine laminectomy as soon as primary shock is over admit that the chances are that little, if any recovery will follow a decompressive operation if the patient has a complete lesion at the very beginning since it is the general consensus that the instant of impact was the moment when damage was created to all practical purposes and that pressure on an already irrevocably damaged cord cannot therefore, add more injury. Others (33) feeling that in many cases anatomical and physiological lesions cannot be differentiated for the first few days even if the effect is one of complete functional loss believe that operation should always follow when there is a block of the cerebrospinal fluid, even without (but especially with) x ray evidence of severe bone injury. All neurological surgeons of experience agree that by general principle it is more allowable to operate in case of injury of the thoracic cord than when the injury is cervical. In the latter case the effects of skeletal traction should always be tried first, and certainly it is generally agreed that early and premature cervical laminectomy within the first few hours or days is bad surgical judgment and is certain to be the one instance in which surgery contributes to the already poor prognosis of the patient.

In the closed type of injury as for instance that resulting from fracture-dislocation in any level of the cord with an incomplete lesion and either with or without evidence of bony compression and especially with such cause for cerebrospinal fluid block, it is well to operate to allow every possible chance for the cord to recover. Certainly when there are signs of progression of neurological symptoms in the incomplete lesion with evidence of compression laminectomy should not be de-

laid. It has frequently been pointed out that after a few hours or days a complete block may exist in either the incomplete or complete lesion without any bone injury whatsoever the block being due to edema of the cord at the level of injury. It has been the general experience that extradural extravasation of blood in significant quantity is a very rare complication. It has also been pointed out that a dissecting hematomyelia is a *fait accompli* and is not reversible by surgery.

Open wounds, such as frequently occur in military casualties, require the usual wound care of débridement but all such wounds require. It was the common practice in the war just past thoroughly to remove all bone fragments and make a clean toilet of the wound, the dura in the potentially infected field never being opened. Indriven spicules of bone and foreign bodies, if accessible, were usually removed. The dural rents were closed either by primary suture if possible, or by the application of living fascial grafts in order to stop the cerebrospinal fluid leak. While wide laminectomy was believed to be the proper operation in the closed injury, it was generally felt that in the fresh open wound only the bone that was actually damaged or in danger of not remaining viable should be removed. The excellent healing and frequent return of function, particularly in the incomplete lesions, which resulted from such treatment of the spinal cord injuries of World War II have given new hope and eagerness to the younger neurological surgeons. As Tinsley has pointed out, such early acquaintance with the actual situation in the cord be it found to be completely severed (a not very common occurrence) or injured to a lesser degree leads to more intelligent later care and permits a more accurate statement of the eventual prognosis. All open wounds, it is agreed, should be treated with the adjunct of chemotherapy but with no direct application of any sulfonamide to the exposed cord.

Certain aspects of the technique of surgical procedure are agreed upon by most neurosurgeons. All agree that insofar as possible only local anesthesia should be used for the operation of laminectomy. As Stoolkey has pointed out, it is unwise to open the dura out of curiosity over a freshly swollen cord if no bone fragments or foreign bodies are to be removed, for the softened cord will only tend to herniate through the dural slit and thus sustain further damage. The occasional article by orthopedic surgeons suggests the attempt at manual reduction of the fracture by means of prying the vertebrae back into position when the laminectomy has been accomplished others suggest further that at this operation the spine be fused.

Both such procedures are called by the neurosurgeons as dangerous and unwarranted. Clark, who advocated manual reduction of the cervical fracture-dislocation at the scene of injury before x-ray studies had been made, also advocated that when laminectomy was performed and the block was found to be due not to bone compression but rather to edema under the cord, a longitudinal slit should be made in the dura to relieve such edema pressure. Palmer stated that laminectomy is attended by a high mortality but this is certainly not the experience of either the neurosurgeons or orthopedic surgeons who perform the operation only when the patient is in proper condition or after the proper period of time in the case of cervical injury. It is the unanimous opinion of all surgeons with experience in the late war that the patient with a spinal cord injury suffers more in the theater of war from the ill effects of transportation than from the shortage of hospital reinforcements that speed and priority of evacuation should be given these patients, and that in the case of the open wound, primary healing of the wound itself and stoppage of the cerebrospinal fluid fistula is of first importance.

Concerning the indications for late operation, Worts and Sharp summarized the opinions of most authors. Cases of intractable root pain secondary to fracture of the spine or of a lamina will occasionally require the attention of the surgeon. In a few instances there may be an indication for late operative intervention in the following conditions: (a) Callous encroachment in the spinal canal giving slowly increasing neurologic signs. (b) Callous encroachment on the spinal roots giving intractable pain not helped by injection of the roots. Such patients may require rhizotomy or cordotomy. (c) Herniation of the intervertebral disc giving back pain, associated neurologic signs and roentgen or myelographic evidence of herniation of the disc. (d) Hypertrophy of the ligamentum flavum with increasing pressure on the spinal cord. (e) Post traumatic adhesive arachnoiditis. It is the repeatedly expressed opinion of many authors that decompressive laminectomy in a case of long standing complete neurological loss below the injury is a futile gesture, even though there is a complete block of the cerebrospinal fluid and demonstrable bony compression. However the occasional surgeon (Rand) does sometimes operate on such patients for whatever beneficial psychological effect it may have and in order to clinch with both the patient and his relatives a statement of the undeniable prognosis. But even those authors who discourage laminectomy at any time for a com-

plete transverse lesion of the cord advocate operation, either early or late for the injured cauda equina, since there the problem is a different one dealing as it does with the more favorable possibilities of the peripheral nerves. Knight, however has made the following unusual statement. It is, of course, unnecessary to remark that even in the case of the cauda equina which it is sometimes suggested should be sutured suture of divided nervous tissue is futile and should not be considered. Even in the cauda the absence of a neurilemma precludes regeneration.

LATE CARE NURSING PROBLEMS

Rehabilitation The time arrives in a few weeks after injury when all active treatment for the injury itself becomes less hopeful. The bone has healed in most patients, and the major problem no longer is one of neurological recovery. The patient must be prepared for an existence as a bed patient (fortunately only a few are in this category) as a wheelchair patient or as a semiambulant patient with the need for crutches, walkers, or braces. World War II has given a tremendous impetus to the re-education of the paraplegic patient, and literature on the present day programs of rehabilitation used principally in the paraplegic centers of several Veterans Hospitals is only recently beginning to appear. These programs are being carried out on a lavish scale but are no more, actually than those which have long been advocated by such authorities as Davis (21 22) Elsberg Coleman and Pilcher (78) Stookey and others (113). Carefully supervised recreation, physical therapy and occupational therapy and study in trade schools are all a part of the general program to improve the morale of the patient, to re-adapt him to a happy and, if possible useful existence and to give him the maximum chance for physical recovery. Therapeutic exercises, and specially made and individually fitted braces are at this time being developed into something of an art, and the great force promoting such a program is, happily the United States Government, as reflected through the care given the paraplegic patients in Army Navy and Veterans' Administration hospitals. It has even been proposed (113) that those paraplegics not wishing to return to their homes or not being able to do so for one reason or another be grouped into communities where they will all look upon themselves as equals, where they will be less the object of pity and curiosity than they are in public institutions, and where they can work toward a semblance of normal existence.

General nursing problems The paraplegic patients present many special difficulties of nursing

care and it may well be said that after the first few weeks they constitute for the most part problems only for the nursing staff and not for the surgeon, although at all times every phase of the convalescent and chronic care should be under the supervision of a competent, interested physician. The government has found that in most instances the primary responsibility of the care should be that of the medical neurologist, with the aid of the neurosurgeon and of the orthopedic, urologic, general, and plastic surgeons as well as of the internist who can consult in problems of general medical care and nutrition. When thus handled this class of patients has apparently required no more special psychiatric care than has any other type of chronic patient. It has been repeatedly pointed out (21 22 26 78 84 113) that the main difficulties of nursing care, other than those of rehabilitation and education, have to do with nutrition of the patient bed sores, and the various complications of the paralyzed bladder. All these and other complications are discussed later in this review. Fay and Munro (69) have insisted along with others, upon the persistent attitude of optimism on the part of all ward personnel who nurse patients with injured cords. A defeatist attitude on the part of everybody concerned must be avoided at all costs. A hopeful, friendly interest approach by the nurse, whom the patient sees more than any one other person is a great factor for good in the comeback of these unfortunate persons.

THE TREATMENT OF COMPLICATIONS

Nutrition Harper (113) has pointed out the necessity of careful supervision by a trained dietitian of the diets of paraplegic patients. He urged a high protein intake, and an average caloric supply of about 2 800 calories daily. It is not desirable for the patient to gain weight particularly in many instances it is desirable to a certain degree since the well fat padded weight bearing points are less likely to develop decubitus ulcers. If such ulcers exist there is a serious loss of plasma proteins in the exudate, and this must be made up by a proper protein intake in the diet. A high vitamin diet is desirable and for the purposes of improving the bladder status a generous fluid intake is also urged by most dietitians.

Decubitus ulcers There is not an author but who insists upon every nursing measure possible to avoid rather than heal (if possible!) the bugbear of decubitus ulcer. There is no place where the ounce of prevention is worth so much more than the pound of cure. It is the unanimous opinion of all writers quoted that to prevent these sores

weight-bearing points must be rested frequently by turning the patient, and by massaging and drying the skin. Sheets must be clean and smooth. The skin must be bathed frequently and kept dry and free from feces, urine, and perspiration. Some surgeons apparently insist that the bedridden patient be turned every hour, others every 2 hours, with care each time to the surface that bore the weight. This, as in all the other care of the patient, assumes a well trained well supervised and willing nursing staff. Attention to the avoidance of decubitus ulcers must begin within the hour after injury and can never for the rest of the patient's existence, be relaxed at any time. Many of the recent articles, stemming from war experience, indicate the fact that delayed and inadequate nursing care during the first few days after injury in the theater of operations, was the main source of bed sores, and it is for this reason among others, that military surgeons have insisted (not always successfully) upon evacuation priority for these patients. It is almost the unanimous opinion of the neurosurgeons that plaster should never be used when it can be avoided, since beneath it sores can and do develop. Others just as strongly advocate its routine use. Apparently some surgeons still think bed sores are an act of God and entirely unavoidable. One author (7) stated that a method of avoiding bed sores was to put the patient in anterior and posterior body shells, from knees to shoulders, and turn the patient 1/2 or 3 times a day.

Once a decubitus ulcer has developed the general care of the patient becomes increasingly difficult. Munro (68) pointed out that the normal vasomotor reflexes of the skin are altered below the level of a spinal cord lesion, on account of a change in the sympathetics, and because of this fact, mild pressure, which would be tolerated by normal skin, quickly causes necrosis as a result of anoxia and anemia due to pressure. The fact that the skin is anesthetic is not the basis for the development of these ulcers. Munro cast out the term "trophic" in the description of these ulcers, pointing out that the same effect is frequently seen in the cachectic but normally sensitive patient who has had the same inattention to the skin. He strongly advised against the use of the Bradford frame, plaster-of Paris jackets, sawdust beds, rubber or other rings and "doughnuts," lamb's wool pads, and other such devices. He recognized the sole importance of cleanly care to the skin and the frequent change of position for the patient, all of which are matters under the control of a willing nursing staff. It is his opinion that no mechanical tricks equal personal nursing attention and that,

of course, is the opinion of all well informed as those who have had extensive experience with the care of decubitus ulcers. Some authors suggest débridement of the ulcer as sloughs appear with simple dressings to the open wound. Munro advised against all incision and drainage of the ulcers, against débridement, and against moist dressings in any form. He, with most others, finds such lesions highly contaminated, but has found sulfa powder dressings useful, as well as painting with tincture of benzoin once daily when the ulcer is not a frank, open, exuding mass. Munro along with others (21, 22, 78) has advised the use of sponge rubber air or water mattresses, and the use of radiant heat and ultraviolet irradiation which has been found to be useful to promote healing.

The plastic repair of decubitus ulcers, once they are relatively free of infection, is successful in a great many cases. As Barker (113) pointed out, in some instances they can be closed by simple excision and primary closure. Some, such as those on the buttocks, will require the use of rotation flaps. Others can be closed by free grafts, although the latter method is sometimes less successful. In the well nourished patient, even extensive sores, if well tended may eventually show granulation and epithelization.

Mass reflexes' spasm contractures Scariff and Pool have recently proposed the interesting theory that the so-called mass reflexes and severe muscle spasm which are the lot of many paraplegic patients are influenced by scar at the site of the lesion on the end of the distal cord segment. They believe that this cicatrix heightens the irritability of the isolated segment of cord, and that removal of the cicatrix, excision of all local degenerated tissue, and surgical section of the dorsal columns in the upper portion of the lower cord segment helps to allay or completely remove this condition. Braden (113) found reason to believe that cure offers some limited improvement in this condition, although its effects are transient and not without undesirable side effects. Elkins and Maltby (113), as well as Munro (79) and others have advocated anterior rhizotomy for the relief of severe spasm, and Munro has given detailed instruction for the technicalities of the procedure. Mayfield (113) recognized the value of the procedure, but advised that it be put off for at least a year after injury or until it was certain that no further neurological recovery would be observed, since the operation is a permanently destructive one. Davis (21, 22) has found obturator nerve section within the pelvis of distinct aid in overcoming the handicap of strong adductor contraction. It has the

advantage of not affecting the leg muscles most used in locomotion and is therefore less destructive in its effects. Along with others Munro has demonstrated that the relief from spasm means that the patient can be made ambulant with the use of braces and crutches, that he is more able to be up in a wheel chair that the development of bed sores is less a threat and nursing care is easier and that, above all, the patient's morale is improved. Tenotomy may be performed for the permanently contracted shortened muscles when all hope of recovery has been abandoned (87).

Pain. Mitchell (113) pointed out that inadequate early operation on the injured cauda equina or the presence of root pain with such injury were indications for secondary surgery and that the removal of depressed bone fragments or foreign bodies with some attempt at restitution of the nerves, would offer relief from the pain which is a common sequel to caudal injury. Others have pointed out that the root pains associated with cervical fracture-dislocation are frequently stopped when adequate realignment of the vertebrae is obtained. Intractable root pain in injuries of either the cervical or thoracic cord can be stopped by adequate posterior rhizotomy. Elkins (113) also pointed out that bony overgrowth the presence of a foreign body post traumatic arachnoiditis, and the spasm itself may be the source of such severe pain that surgical relief is necessary. When the cause can be removed this should be done when it cannot posterior rhizotomy or cordotomy (also 78) on the spinothalamic tracts should be performed. Care must be taken that additional injury to the motor tracts or an increase in the spasm is not produced by technically inadequate cordotomy. The role of the sympathetics is not understood by most surgeons and many patients with apparently complete lesions complain of unrelenting burning pain which is not controlled by such questionable methods as novocainization of the sympathetics. It has been found too that many times such vague and pathless 'pain' has a strong functional element, and can be overcome by re-directing the attentions and interests of the patient. All are agreed that these patients should not be made drug addicts.

The bladder. The care of the bladder paralyzed by a spinal cord injury is a subject for great controversy between urologists and neurosurgeons, and between neurosurgeons. A review of the literature makes apparent the fact that most urologists consider the care of the bladder under such circumstances as a purely urological problem, some urologists and neurosurgeons consider it a joint problem and some neurosurgeons

believe that it is a neurological problem and they therefore do not seek urological consultation. All authors agree however, that the care of the bladder is a major problem that it is a complication of the injury from the moment of the trauma, and that much of the success or failure of later bladder function depends upon the proper initial care.

It has been pointed out (63 64 115) that the appalling death rate among British casualties in World War I suffering spinal cord injuries was due to urinary sepsis and it is the belief of many British authors that this now somewhat embarrassing fact was due to early repeated manual catheterization. If one is to judge by articles dealing with the care of the bladder in the casualties of World War II it would seem that the method of choice was early suprapubic drainage with a large tube and the fistula placed well above the symphysis pubis later when the patient reached adequate hospital facilities, the tube was removed and replaced with a permanent indwelling catheter. It has often been said that the suprapubic tube is placed for purposes of transportation but it has been the experience of more than one surgeon to receive the patient at the base hospital with urine oozing out around a plugged up suprapubic tube (which promoted the formation of bed sores) with a necrotic fistula, or on occasion, with the long unattended tube simply rotted off and lying free in a mass of calculus in the bladder. Certain authors (2 51 116) particularly among the British dislike all apparatus which must be fixed to the penis. They describe a 'trocar' method of performing the suprapubic cystostomy with insertion of the tube immediately above the symphysis a method most unpopular in America. Tidal drainage generally popular in America, has been found by many to be unreliable dangerous when it does not work properly, and requiring too much close attention (2 8 114). In fact, Taylor believed he could trace 2 deaths directly to the use of the tidal drainage apparatus, whereas Munro America's first proponent of the method quoted figures showing a sharp decrease in morbidity and mortality through the use of this method. Browder and Grimes (8) are among the few neurosurgeons who advocated the use of manual expression a method long in favor among British urologists and some British neurosurgeons. They (8) stated 'In an effort to eliminate the use of the indwelling catheter we have extensively employed manual expression of the urine by suprapubic pressure. Furthermore, the use of this procedure facilitates the establishment of automatic urination. Detailed instructions are given for the employment of this method and they go

on to say. Although the bladder cannot be completely emptied by this method, infection is extremely rare.

The intelligent co-operation of the staff (nursing) is a prerequisite if successful results are to be expected. An obese abdomen precludes the possibility of manual expression of the urine by suprapubic pressure. Elderly patients who may have thin vesicular musculature possible diverticuli of the bladder or urethral obstruction from hypertrophy of the prostate should never be treated for urinary retention of traumatic origin by this method. Oldberg has rarely seen the development of a true automatic bladder.

Munro (65-73) Scarff (102) and others have described in detail the construction, uses, and applications of the tidal drainage apparatus. They do not indicate that it is a simple self regulating mechanism, but they recognize in it a means of continuous cystometric study and a means of keeping at a minimum the bladder infection which is bound to occur medication notwithstanding when any foreign body such as a catheter is placed in the bladder and they believe that some such continuous method of drainage is essential. They point out, too, that it is the only certain and safe means of training the bladder into automatic function, provided the injury is one of the cord and not of the cauda equina.

The various methods of treating the bladder are, in summary noninterference and letting the bladder distend until it overflows (if it will before rupture) as some authors have cynically pointed out) aspiration of the bladder with a large needle directly through the abdominal wall until some better method can be employed manual expression repeated intermittent catheterization use of the simple indwelling catheter which is allowed to drain freely use of the indwelling catheter which is opened for drainage every 4 hours, following which the bladder is allowed to collect a certain amount of urine by the closing of the stop cock suprapubic cystostomy perineal cystostomy with an indwelling mushroom catheter and use of the indwelling catheter with tidal drainage. The literature shown in the references to this review is replete with strong arguments for these various methods or against them, and the authors' views are illuminating reading.

Hinman, one of America's senior urologists, in a concise and instructive article has stated the problem very well. "The usual course of the effect on micturition of a transverse lesion of the cord at any level is first, retention, second, overflow incontinence, and third, automaticity. Automaticity never develops with destruction of sacral segments or cauda equina. He stated that actu-

ally there was reason to choose variously between the many methods of treatment, since all had their virtues and the particular case might demand one or the other procedure. He felt that the dissenting authorities were as reliable as those arguing for the use of noncatheterization and manual expression suprapubic cystostomy or retention catheter with or without tidal drainage. He only stated categorically that no paralyzed bladder should be let alone to distend and overflow and the urethral catheter should never be used casually or intermittently. Other than for the primary purpose of allowing the escape of urine bladder care need be concerned only with the prevention of sepsis and wetting of the patient with the resultant bed sores. The paralyzed bladder he believed, is strictly a urologic problem.

Hinman feels that manual expression is the one method of avoiding infection, but that its use requires a skill and regular attention not frequently found in nursing staffs. If infection does exist, the use of manual expression may cause an ascending pyelonephritis. Furthermore, the bladder may be ruptured. It is best never to resort to manual expression if the patient has at any time been catheterized. All in all, he feels that the suprapubic tube is the method of choice, and this is a common expression among urologists. Petroff (113) and others have agreed with most neurosurgeons that the suprapubic tube does not necessarily guarantee the least urinary infection for the patient, and that it is not the driest method by any means. He, with many others, has found that the early change from a suprapubic tube to an indwelling catheter was a great boost to the patient's morale, for he found that the suprapubic tube was repugnant to most patients. He advised the usual current method of placing a Foley catheter, small enough to allow the escape either into the bladder or externally of the urethral secretions, frequent cystometry and daily irrigation with "AI" solution or some other suitable bladder antiseptic. It is frequently pointed out that acid urine is the less septic, and the fluid intake of the patient should be at least 3,000 c.c. daily.

Emmett (29, 30) has recently advocated transurethral resection of the vesical neck in the management of cord bladders and actually this procedure has been in effect for some time in the hospitals of the Army Navy and Veterans Administration. In discussing the reasons why there is always residual urine in the "cord bladder" he stated "Modern urologic thought has suggested a more attractive and rational explanation. Inasmuch as it has been shown that no true internal vesical sphincter exists, it is assumed that the

vesical neck is simply the edge of the detrusor muscle and therefore takes part in the spasticity, hypertonicity and hyperplasia of the detrusor muscle as a result of transverse lesions of the cord. It is reasonable to assume that this muscle may act as an obstruction at the vesical neck and may be a considerable factor in the inability of the bladder completely to empty its contents. As time passes this condition may be aggravated by infection and subsequent fibrosis of the vesical neck. Such an explanation sounds logical. If it be correct, then transurethral resection of the vesical neck should offer a good chance of cure.

Petroff (113) has discussed the use of penicillin, the sulfonamides, and other new antibiotics in the control of urinary sepsis. Joelson and Hamm (113) have summarized well the problems concerned with the prevention and treatment of urinary calculi.

SUMMARY

The paraplegic patient with his problems has been brought into the consciousness of the lay and medical public with a tremendous impact by the large number of such casualties incurred in the recent war. One has only to read of the medical experiences in the care of these patients after World War I and then the recent reports of the accomplishments under modern conditions to realize how much has been accomplished in the interval in the cure and rehabilitation of these patients. One also finds, as already indicated, that a wide divergence of opinion still exists, centered mainly about 2 problems: (1) When is the patient to be operated upon for decompression of the cord? and (2) What is the proper care of the paralyzed bladder? One finds the attitudes range from the eager humanistic hopefulness of men like Temple Fay and many other younger surgeons with the experience of World War II, through the conservatism and latitude of opinion of such authorities as Coleman, Pilcher and Meredith (13, 78) Davidoff (20) Davis (21, 22) Oldberg (80) and others to the stark realism, even pessimism, of equally reliable surgeons as Elsberg (27) and Naffziger (74). It is generally agreed that the care of the paraplegic patient is in the main a nursing problem, but a nursing problem which in its many ramifications takes the constant supervision of a well trained, interested, energetic, and open-minded doctor. It is a nursing care crammed with meticulous detail, all of which must be religiously followed.

As already indicated in the literature there lurks many a statement which is patently false or even ridiculous and which should be pointed out to the unwary. To understand the care of the pa-

tient with an injured spinal cord a fundamental knowledge of neurology is an absolute essential. It is not a mechanical problem. It is not a problem to be covered by 'standing orders' or an attitude of 'let the nurses do it.' The paraplegic patients are here, and the problems of their care and treatment must be thoughtfully carried to their solution. There is no doubt but that these patients have been played up too strongly in the public mind. They have become the center of much interest, not medical, which may eventually make their management even more difficult. The very word 'paraplegic' is objectionable. It is frequently heard nowadays from the lips of patients and lay persons singling out, stamping and labeling these patients as doomed with a special and hopeless disability. Therefore, a less pointed less specific term should be adopted. These patients are seriously tragically injured persons, and should be treated as such but they should not be singled out from those with other types of injury for overindulgent publicity. They are before us as a medical problem to be continuously wrestled with. To quote Pilcher:

'Like Humpty Dumpty the spinal cord can never be put together again! At first glance this gives the subject a hopeless case and suggests that this paper might better be left unread. However, such a defeatist attitude would neglect the possibilities of prevention of further associated bony injuries, of palliative therapeutic methods, of avoidance of complications, and of adequate diagnosis with its resultant correct choice of therapy and accuracy of prognosis. In no field of surgery are the results perfect. Only by continuous study of our unsolved and seemingly impossible problems may further progress be made. To the neurosurgeon this is not a strange difficulty.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Marino, H., and Crawlott M: Fracture of the Mandible (Fracture de la mandibule) *Press med. argent.*, 1946 33 1833

In common fractures of the mandible situated in the horizontal rami it is enough to fix both dental arches with ligatures to obtain excellent results but when dental fragments are absent and the fracture is situated behind the angle of the mandible the integrity of the maxillary arch which serves as the immobilizer is lost and difficulties arise. Intraoral appliances always fail because it is impossible to obtain good control of the ascending ramus which is pulled upward by the violent force of the pterygoid muscle.

Rainsford Mowlem the English plastic surgeon, used the method of Roger Anderson, Le reducing and fixing the bone fragments with pins or screws.

This method of treatment is indicated in the following conditions: fractures in the toothless with great displacement fractures behind the dental arch and fractures complicated by injuries of the face with lesion of the superior maxillary arch impeding intraoral prosthesis fractures without fissures which cannot be fixed by dental arches comminuted fractures with destruction of the osseous segment greatly displaced fractures and those in which intraoral treatment is no longer possible fractures in patients to be transported by sea or air and in those with vomiting fractures with great trauma of the face, accompanied by loss of substance and in which grafting is required and exposed comminuted fractures subject to early removal of bone splinters.

Contraindications to this method are suppurative processes near or in the line of fracture or zone of insertion of the pins, fractures of the neck or the coronoids and sometimes the character of the bone.

The advantages are permanent and effective immobilization conservation of the masticatory function and acceleration of consolidation avoidance of articular rigidity facilitation of buccal cleanliness and feeding. Gingivitis and irritation by intraoral methods are avoided the patient is comfortable and without pain and the appliance is easily covered by a handkerchief or muffler.

The apparatus consists of 3 or 3 metallic walnuts formed by a central screw and two canalized hemispheres with a middle piece intermediate bars of union unoxidized steel wire pins and a wrench to tighten the screws.

The authors first secure a good roentgenogram showing the arrangement and relations of the neighboring dental fragments. Complete muscular relaxation is desirable. It may be obtained by means of intratracheal anesthesia or as preferred by the authors

by local novocaine infiltration. The index finger is introduced into the mouth while the fingers of the other hand delineate the fracture externally and the assistant marks the posterior and inferior borders of the mandible with methylene blue or brilliant green. It is advantageous to insert the pins close to the line of fracture (about 1 cm.) but it is not always possible. They must be inserted at least 0.5 cm. from the inferior or posterior border so as to avoid the dental foramen with its nerves and vessels. To introduce the pin a mechanical or electric drill is used or the skin is perforated with a sharp pointed temperure is provided by the intraoral finger. Drilling should be done slowly to avoid heat necrosis of penetration, may or may not be used. For better control of the fragments the two pins should have a distance of 1 cm between them. On the pair of pins corresponding to each fragment the squared half walnut is secured and the two pairs are fixed firmly with an intermediate bar which is fastened to the other canalized half walnut. It is not always possible to retain the ideal reduction, so it is wise to add an intermediate walnut formed by two canalized half walnuts and to use two smaller bars to obtain an adaptable universal joint. The simple external dressing is a small roll of gauze twisted at the level of the point of entry to the skin. Some surgeons apply a temporary interdental ligature or a sling bandage which is not necessary in the majority of cases. Clinically the walnuts are loosened and roentgenographic control is verified. The pins are extracted with pliers. The residual scar is minimal.

The authors cite the case of a patient with fracture at the inferior maxillary angle. His upper maxilla was entirely toothless there were some teeth in the anterior portion of the lower jaw and a right molar was present. On the left side where the trauma occurred there was a second molar and the root of the third molar passed through the line of fracture. The lesion had been suppurating for 12 days when the patient was first seen and there was a fistula in the region distal to the second molar. The pus was evacuated externally and the jaw was immobilized with penicillin was given. The pins were removed after 32 days the result was good. A. B. VINCIGLIO MD

Stewart, M. B. and Conley J. J.: Fractures of the Malar Zygomatic Compound: Treatment by Improved Methods and Myoplasty *Arch. Otol. Rhinol. Laryng.*, 1946 44 443.

The authors review the history of fractures of the malar zygomatic compound and discuss some of the

more popular methods of treatment in use at the present time.

The symptoms and signs of a fracture of the malar sygmatic compound are (1) pain (2) periorbital swelling and depression or flatness of the face (3) pain on mastication (4) trismus, if the arch is involved (5) intranasal hemorrhage on the injured side (6) diplopia (7) emphysema (8) a palpable depression extending into the orbit (9) subconjunctival hemorrhage and (10) neurological changes resulting from damage to the infraorbital nerve.

The four principal sites of fracture correspond to the articulations that is, (1) at the superior external orbital margin (2) the region of the infraorbital foramen, (3) the sygmatic arch and (4) the sygmatic process of the maxilla.

The authors mention the principal methods of treatment of simple depressed fractures of the sygmatic arch the first method being that of Blasas, in which a silver wire passed under the sygmatic arch and twisted over an external padded splint is used to hold the fragment elevated and in position.

Keen's intraoral approach through the buccal fold over the upper second molar is described briefly. This consists of elevating the fractured arch and maintaining this reduction by means of a lubricated pack.

The method of Manwaring and Gill consists of elevating the fragments by grasping the sygmatic fragment with a medium sized towel clip and manipulating it into position.

The Gillies method or temporal approach is the method of choice. It consists of making a horizontal incision over the temporal muscle and passing an elevator beneath the temporal fascia under the sygmatic bone. The skull is padded and used as a fulcrum and the fragments are manipulated into position. Approximately 95 per cent of the fractures of the arch can be reduced by this method.

In the treatment of malar fractures, manipulation is more difficult and fixation and traction are frequently required. The fragments are often impacted and reduction cannot be delayed as long as with a fracture of the sygmatic arch.

Roberts makes an incision over the malar eminence and elevates and manipulates the malar bone by using a corkscrew like instrument.

Fixation of the malar bone can be accomplished occasionally by direct wiring with tantalum wire. When traction with external fixation is needed a plaster of Paris head cap is constructed and a screw eye is inserted through an external stab incision into the malar fragment and held in position for about a week.

Lothrop's method consists of the antral approach with elevation of the malar bone and packing of the antral cavity.

Associated fractures of the maxilla can be reduced without a cumbersome head cap by internal fixation with wire this being placed through the orbital rim and through the soft tissues to be fastened to the teeth. These wires are left for several weeks and are then removed by opening the original incision, cut

ting the wires, and pulling them out through the mouth.

The author enumerates the more common complications of fractures of the malar sygmatic compound. These are diplopia, nerve injuries, hematoma in the maxillary sinus, and contracture of the masseter muscle. A special method of correction of the last named complication is described. This consists of a myoplasty in which three through-and-through transverse incisions are made in the masseter muscle at the sygmatic end one of them being in the anterior third and one in the posterior third of the muscle at the point of attachment to the sygoma. The third incision is made through the middle third of the muscle at some distance below the first two. This allows for greater opening of the mouth.

LOUIS T. BRAYS, M.D.

EYE

Duggan, W. F.: Vascular Basis of Allergy of the Eye and Its Adnexa. *Arch. Ophthalm., Chic.*, 1946, 36 551

The author has reviewed the literature of allergy from the viewpoint of the etiological importance of histamine or histaminelike substance. His concept of allergy is that some influence, either chemical, nervous, humoral or climatic, through histamine, a histaminelike substance, epinephrine nicotine or over action of the sympathetic nervous system causes a smooth muscle spasm, capillary dilatation or both. The arteriolar constriction and the capillary dilatation cause a slowing of the blood stream in the capillary bed with a resultant capillary and tissue anoxia. The capillaries next become more permeable as a result of either lack of oxygen or of opening up of the spaces in the capillary walls and allow the passage of plasma, fibrin, white cells and red cells through their walls.

Since it has been shown that nitrites are beneficial in the treatment of anaphylactic shock and that there is a capillary and tissue anoxia, and since the author concluded that oxygen is a physiological antidote for histamine he reasons that drugs which increase the oxygen to those tissues should be of value therapeutically. He therefore used vasodilators in the form of sodium nitrite, amyl nitrite, erythritol tetranitrate and acetylcholine bromide in the treatment of conditions thought to be on this basis. The rationale was that it would reduce not only the offending agent, but also the resultant deficiency in oxygen. Foreign protein therapy was thought to be too dangerous and too likely to cause further allergic reactions.

Various eye diseases were then considered as being of possible allergic etiology. It is believed that acute glaucoma is a manifestation of capillary and tissue anoxia, and has the same pathological picture as that of histamine and allergy; and that if acute glaucoma is an angioneurotic edema of the eye it is due to histamine formed elsewhere and transmitted to the ciliary body where it acts on the capillaries and possibly the arterioles. In the

author's opinion the relief of anoxia by amyl nitrite accounts for some good results in the treatment of acute inflammatory glaucoma.

Herpes corneae, herpes zoster and herpes indolens are suggested as being allergic lesions on the basis of the typical pathology of allergy in the grassian ganglion. This could be caused by histamine and treatment with vasodilators gave good results.

Various types of paralyses of ocular muscles may be due to allergy with consequent angiospasm and closure of one of the retinal arterioles with its result in some cases of an allergic reaction in its simplest form. The possibility of an allergic basis for the pathology of multiple sclerosis is considered. It is thought that the local circulatory failure causes the myelin breakdown and that the gliosis of retinobulbar neuritis was that of multiple sclerosis.

The causes of iritis and iridocyclitis are listed and it is noted that all had vascular dysfunction in common thought to be allergic in nature. Acute exudative choroiditis and choroiditis serosa centralis are classed in this group. The pathological picture of scleritis and episcleritis was also suggestive of allergy.

The author has had excellent results in the treatment of these cases with vasodilators and he believes that although the treatment is nonspecific as regards the cause it is specific as regards the pathophysiological basis of the lesion.

McLaughlin R. S. ; Chemical Burns of the Human Cornea. *Am. J. Ophth.* 1946 39 1355

Foster J. ; Certain Operations on the Superior Oblique Muscle. *Br. J. Ophth.* 1946 30 696

In the past Von Graefe had considered it better judgment not to operate on the oblique muscles. Since then myectomy recession and resection of the inferior oblique muscles have all been frequently performed with success although there has been relatively little surgery of the superior oblique muscle. Because of this relative rarity the author has reported 3 cases of surgery of the superior oblique tendon.

The first case was that of a man who had been hit in the forehead well above the orbital margin. Following this blow there was a paresis of the left superior oblique muscle resulting in a vertical diplopia in the whole lower field. Vertical prisms were of some benefit and orthoptic exercises were given. Later a partial tenotomy of the right inferior rectus muscle was done but the patient continued to have by periorbital and cyclophoria. Because of this, the inferior oblique muscle was tenotomized by the Dunnington method. The superior rectus was divided to expose the superior oblique. A double armed catgut suture was inserted through the superior oblique tendon about 6 mm. from the insertion. This point was attached to the episclear tissue of the globe in

the line of the muscle without dividing the insertion. This, then, was more of a tuck than a real advancement. The results were most successful clinically but there was a slight postoperative weakness of the left superior rectus muscle and residual overaction of the right inferior rectus and inferior oblique muscles.

In the second case the patient had had a basal skull fracture with a resultant paralysis of the fourth and sixth nerves. Surgery which included a 6 mm. recession of the internal rectus and inferior rectus of the lateral half of the superior and inferior rectus of the insertion of the external rectus and a 6 mm. tuck of the superior oblique tendon to its insertion was performed on the left eye. The results were satisfactory except for a restriction of the internal rectus muscle.

The third case had a marked limitation of the inferior rectus muscle of the left eye as a result of a penetrating injury in the orbit. Surgery of the inferior rectus was not satisfactory because of marked fibrosis and adhesions. An 8 mm. recession of the right superior oblique muscle was done with fairly satisfactory results.

McLaughlin R. S. ; Chemical Burns of the Human Cornea. *Am. J. Ophth.* 1946 39 1355

A chemical burn of the cornea was defined as an injury which results from local contact with a chemical to such a degree that there is alteration in the structure of the cornea and conjunctiva as demonstrated by a positive stain with 2 percent fluorescein. The author reported on a series of 500 consecutive cases of this type. He found that 54 per cent of the injuries were caused by vapors and mists, 31 per cent by liquids, and 17 per cent by solids.

Because immediate care is of first importance a system of first aid was carried out by the industrial plants. The workers were instructed to wash their eyes thoroughly at one of the handy eye washing fountains. They were then taken to the dispensary where the type and pH of the offending agent were recorded. The eye was anesthetized gross particles were removed, and the eye was irrigated with a copious flow of normal saline solution for 15 minutes. Fluorescein was instilled and if the eye stained it was again washed for 15 minutes.

The patient was referred to the ophthalmologist for further irrigation, debridement, the instillation of postoperative and sulfathiazole (or sulfadiazine) ointment and patching. However it was found that certain chemicals, namely alkali and a few neutral organic compounds had a delayed action. These organic compounds frequently caused opacification of the cornea and adhesions of several hours after using a symptom free period of the conjunctiva follow grayish self defined areas in the superficial layers of the corneal epithelium. It was thought that the foreign compound was first physically absorbed by the protein structures of the cornea. Then a portion of the absorbed chemical denatured the cellular pro-

tein which resulted in a liberation of the remaining unaltered chemical, and this in turn caused more damage both to the epithelium and Bowman's membrane.

Since in animal experimentation attempted neutralization caused no amelioration of the injury the cornea and conjunctiva were completely denuded of epithelium in the staining areas. This was done thoroughly with a cotton swab under cocaine anesthesia after which the eye was flushed with stainless merthiolate. By this method it was hoped that all the offending agent was removed. After acid and most neutral chemical burns, the eye was just debrided and irrigated. Then all types were treated with pontocaine and sulfathiazole (or sulfadiazine) ointment and patching. Homatropine was reserved for those who were not doing well on the second day. The instillation of methylene-blue powder and atropine, the use of foreign protein and sodium salicylate, and a search for foci of infection were begun if healing was not complete on the third day. The author believed that more vision was lost in chemical burns because of foci of infection than because of the actual effect of the offending agent.

Of these 300 cases, 91.3 per cent healed in 48 hours, 7.4 per cent healed slowly and 1.4 per cent healed with a residual loss of vision. The last 7 cases were reported.

ROOFA H. JONASOW, M.D.

Carpenter, C. P., and Smyth, H. F., Jr.: Chemical Burns of the Rabbit Cornea. *Am. J. Ophth.* 1946, 29: 1363.

This study was undertaken to help in estimating the damage to an eye by various chemicals and in the hope of instituting more rational therapy.

The authors first graded the severity of the eye burns resulting from a large number of chemicals and mixtures instilled in rabbits' eyes. This grading was based on the appearance of the cornea and iris before staining and on the area of the cornea that stained. The grading was felt to be reliable because the higher the score the longer the eye took to heal and because the higher the concentration of the chemical used the higher was the score.

To test the various chemicals and their dilutions a measured amount of fluid was instilled in a proved normal eye of an albino rabbit. The eye was examined from 18 to 24 hours later and the injury was scored. A total of 180 chemicals were arranged according to the grade of injury and listed in a table.

Since it has been thought that neutralization of acid or alkali burns is good treatment, the authors burned rabbits' eyes with acetic anhydride and then treated them with milk of magnesia. They found that milk of magnesia was of no benefit and did harm in some cases. They then burned rabbits' eyes with sodium hydroxide and irrigated them with 2 per cent acetic acid or 0.85 per cent saline solution. There was considerably less damage to the eye that was irrigated with saline solution alone. It was then found that citric acid in 2 per cent and in 0.5 per cent solutions damaged normal rabbit eyes.

The authors divided chemical burns of the eye into three categories, namely those produced by neutral, acid, and alkaline agents. In this article they investigated alkaline burns of the cornea. It was found that alkaline (and some neutral) agents caused a delayed damage to the eye even after prolonged irrigation. The authors were able to show that a rabbit's cornea retained a higher pH following a sodium hydroxide burn even after prolonged irrigation. This was demonstrated with a sealed hanging-drop preparation of corneal tissue and with a glass electrode. An *in vivo* test was devised in which the cornea of one rabbit was burned with sodium hydroxide and then well irrigated. A superficial section of this cornea was removed and placed on the eye of another rabbit for 1 hour. Repeated tests showed that the recipient eye had a higher pH when treated with a burned cornea than when treated with a section from a normal cornea. From this it was concluded that the alkaline molecules reaching the cornea are bound in some fashion to the epithelial cells and are not removed by prolonged washing with saline solution or water.

Since McLaughlin had experienced good results by removing the epithelium of human eyes which had been burned by alkaline material these authors applied the same technique to the experimental alkaline burns of the rabbit cornea. They found, contrary to McLaughlin, that any mechanical interference retarded rather than hastened the natural healing process in rabbit eyes.

ROOFA H. JONASOW, M.D.

Arruga, H.: Detachment of the Retina: Pathological and Therapeutic Considerations. *Arch. Ophth.*, Chic., 1946, 36: 531.

Detailed studies of the ocular fundus, and histological examination have demonstrated that in cases of idiopathic detachment the retina is much altered. In many eyes which have not had detachments, atrophic and degenerative lesions which reduce the thickness of the retina (histologically) to one-third normal are seen. In some eyes retinal holes have been seen without retinal detachment. Therefore many eyes are predisposed to detachments but do not develop them. It is thought that an adhesion of the retina to the vitreous is necessary to raise and jerk the retina away from the choroid, but if the retina and choroid are tightly adherent, the retina will not detach in spite of this. Trauma is now considered less important than it was formerly. Small tears have a more rapid resorption of the subretinal fluid and a better prognosis than large tears or dissections.

Another factor in the formation and cure of detachments is the condition of the choroid. It is thought that little change in the choroid is required to make a detachment possible. A detachment which is replaced by rest has a good prognosis, since the choroid has shown that it is in good condition for reabsorption of fluid. This is necessary for the absorption of exudation caused by future diathermy. If

the choroid does not absorb the subretinal fluid well, the prognosis is not as good. There is also a variable response of the choroid to diathermy: those with less response (no uveitis) have a better prognosis. For this reason it is advisable to localize the diathermic action as much as possible. Immediate reoperation of the operation is advisable only when tears appear which were not reached by the preceding diathermy.

Bed rest and binocular bandaging both before and after surgery improve the results of treatment.

ROGER H. JOHNSON, M.D.

Wilder, H. C.: Intraocular Tumors in Soldiers. *M.D. Surgeon* 1946 99 459.

The author reports that he found a number of intraocular tumors in healthy soldiers from 18 to 38 years of age during World War II. True intraocular and potentially neoplastic tumors occurred in 42 (1.08%) of a series of 3,882 enucleated eyes of soldiers who were examined during the period between Pearl Harbor and VJ Day at the Army Institute of Pathology.

The reported series of cases includes benign and malignant melanomas of the uvea, bilateral intraocular metastases from pulmonary carcinoma and from malignant skin melanoma, malignant dyskeratosis in a traumatic intraocular epithelial implant and Von Hippel's disease.

The type of tumor most commonly observed was a malignant melanoma of the uvea, next in frequency was the benign melanoma. Benign melanoma of the choroid was found in several eyes which were enucleated following trauma—in 1 case of phthisis bulbi and in 5 cases in which the condition would probably not have been diagnosed in civilian life. Carcinoma of the choroid rarely metastasizes from the lungs. Melanomas in patients under 40 years of age are believed to be less malignant than those which occur in the later decades of life.

The author points out that the percentage of cases of intraocular tumors of the type usually observed was surprisingly low for the large number of patients examined.

JOSHUA ZUCKERMAN, M.D.

Sorsby, A. and Ungar, J.: Pure Penicillin in Ophthalmology. *Brit. M. J.*, 1946 2 713.

The authors discuss the value of pure penicillin in ophthalmology. Pure penicillin (calcium or sodium) salt is a white crystalline substance which is freely soluble and more stable than commercial (impure) penicillin, and remains stable for months at room temperature. One milligram of pure penicillin corresponds to 1,660 Oxford units. Whether applied locally to the eye as an ointment (containing up to 100,000 units per gram) in aqueous solution intra-vitally, or subconjunctivally, pure penicillin is well tolerated. By the introduction of concentrated ointments into the conjunctival sac, adequate therapeutic levels of penicillin can be obtained in the aqueous. To obtain higher levels, subconjunctival injection is necessary. Systemic administration of massive doses will yield adequate although evanescent, levels

Adrenalin added to the subconjunctival injection increases persistence; beeswax for intramuscular injection helps to sustain the level of concentration.

Experimentally infections of the anterior chamber are readily controlled by the use of concentrated ointments; subconjunctival injections and systemic administration of penicillin. Infections of the vitreous are satisfactorily controlled only by subconjunctival injection.

Clinical trials show that the experimental results are applicable to man. JOSHUA ZUCKERMAN, M.D.

Harrington, D. O.: Autonomic Nervous System in Eye Disease. *Am. J. Ophth.* 1946 29 1405.

In this article the author discusses the clinical manifestations of certain functional and organic eye conditions which have as their common etiology dysfunction of the autonomic nervous system.

Various conditions in which this subject could be clinically studied were illustrated by patients having (1) central angiospastic retinopathy (2) ocular changes associated with Raynaud's disease (3) amaurosis fugax (4) commotio retinae (5) migraine (6) concussion retinopathy (7) blast concussion retinopathy and (8) solar retinitis. The autonomic stimulæ are enumerated and the importance and frequency of psychic trauma as a cause of autonomic instability are shown. HURTER H. ROMANET, M.D.

EAR

Brown, J. B., Cannon, B., Lischer, C. E., Davis, W. B., and Others: Further Reports on the Use of Composite Free Grafts of Skin and Cartilage from the Ear. *Plast. Reconstr. Surg.* 1946 1 130.

Losses of the ala, columella, or tip of the nose, due to trauma, burns, wounds, or operative causes have always presented a problem in repair. Correction has usually necessitated the utilization of local flaps which may alter a normal feature on, or adjacent to, the nose, or it may be necessary to transfer a remote flap which requires multiple procedures.

The use of a free transplant from the ear, comprising two surfaces of skin with cartilage between, has made possible these corrections in a single procedure. There is minimal deformity of the ear which is repaired either by closure of the defect, grafting of the raw surface, or the use of a scalp flap.

Further experience with the use of composite free grafts from the ear in columellar tip and nostril margin repairs confirm the initial enthusiasm for this method. A total of over 50 operations of this type have been performed with failure in only 4 instances.

MOUTH

Maxwell, M. M., Schork, C. J., and Heldt, E.: The Rationale of Treatment in Maxillofacial Injuries. *J. Oral Surg.* 1946 4 369.

The dual purpose of this article is to stress the necessity of adhering to a logical sequence of treat-

ment factors in the successful management of complicated jaw injuries and to emphasize pertinent fundamentals of concern to the oral surgeon.

In hospital practice the handling of these cases is a mutual responsibility of various services, of which the dental the plastic or orthopedic, and neurosurgical play the principal roles. It is of the utmost importance that the closest possible liaison exist between these services in the development of a rational plan of procedure. When a number of operations are involved in a case of maxillofacial reconstruction these operations should be performed in a sequence conducive to the best end result. For example it would be inadvisable to make a plastic repair on a collapsed jaw and thus render it more difficult for the oral surgeon to restore masticatory function. Conversely, it would be equally inadvisable to attempt immobilization of the jaws in the presence of severe systemic disorders requiring precedence in treatment.

Experience gained from World War I demonstrated the need for maxillofacial teams composed of various specialists working closely together to serve the best interests of the patient. Reports indicate that these teams, as used in the Services, have made a substantial contribution to improved treatment in World War II. However it is believed that even better results are possible of attainment when the various specialists making up these teams have a broad understanding and some training in mutual fields of endeavor. The establishment of treatment centers staffed by competent co-operative maxillofacial teams seems to be the solution to the problem of providing the best possible attention and care for the more complicated cases of face and jaw injuries.

The time of treatment for maxillofacial cases is frequently as important as the nature of the treatment rendered. Indeed it may be said that favorable prognosis for these cases is dependent upon two factors: the time of treatment as well as the nature of the treatment. With the passage of time if no treatment or simply symptomatic treatment is rendered, the prognosis becomes progressively more unfavorable. It is obvious that definitive treatment for these cases is considerably handicapped by the formation of cicatricial tissue by bony consolidation in malunion and by the inception of avoidable infection.

This article is divided into four parts with emphasis upon the oral surgeon's responsibilities at the time that maxillofacial cases come under his care.

Four cases are presented with many photographs and detailed descriptions of the management of each case.

JOHN F. DELPE, M.D.

Bernier, J. L., and Thompson, H. C.: The Histogenesis of the Cementoma. *Am J Orthodont.*, 1946, 32: 543.

Fifteen cases of cementoma are reported and discussed. This material is presented with the suggestion that the reaction of the periodontal membrane in the production of the cementoma may be

essentially similar to the process resulting in the formation of ossifying fibromas fibrous osteomas, and fibrous dysplasia of bone.

If this analogy is true, then one is not entirely justified in assuming that the cementoma is a rare tumor. It likewise becomes important then, to place more stress on the histological analysis of such lesions if an accurate diagnosis is to be forthcoming.

NOAH D. FARRICART, M.D.

PHARYNX

Reeves, E.: Hemostasis after Adenoid Operations. *Laryngoscope*, 1946 56 616

Formerly there was a greater percentage of tonsil bleeding than of adenoid bleeding than at present following a tonsillectomy-adenoidectomy operation. The greater incidence of adenoid bleeding today may be explained by the fact that greater care is now made to stop tonsillar fossa bleeding completely while bleeding from the adenoid fossa is somewhat neglected. Postoperative bleeding from the adenoid fossa can be very serious and difficult to control. Therefore, more care should be taken to stop completely all bleeding before the patient leaves the operating room.

Care should also be taken before operation to rule out any blood or infectious disease which may cause bleeding. It is better to avoid adenoidectomy in any case of elevated fever during the menstrual period in the presence of secondary anemia or during the treatment of syphilis by arsenic or bismuth. It is advisable to determine the bleeding and coagulation times of all patients prior to operation.

There are 3 generally accepted methods of hemostasis after adenoidectomy and tonsillectomy: the plain ligature, the suture ligature, packing, electrocoagulation and infiltration of the tissues with novocaine and adrenalin.

Reeves gives a detailed description of the anatomy of the nasopharynx and distribution of the pharyngeal tonsils. The blood supply and venous drainage is briefly discussed.

There are several methods of doing an adenoidectomy. Reeves uses the method described by Fetterolf with slight modification. This consists of removing the adenoids with a LaForce adenotome following the tonsillectomy. A curette is then used, if necessary. A Tlemann elevator is then introduced to obtain a view of the fornix and a punch of the Myles type is used to remove any remnant of adenoid tissue, loose mucosal tags, and the thick infiltrated mucosa of the posterior wall.

Following this, any bleeding from the tonsillar fossa is stopped and the adenoid fossa again examined. If any bleeding is present, it is usually from the edge of the cot mucosa. The author describes in some detail the application of a modified Conkley slipknot of No. 1 plain catgut to stop this bleeding. If bleeding is present from an area where a plain ligature cannot be used, a suture ligature may be of value, but care must be taken not to injure the im-

portant levator veli and salpingopharyngeal muscles. The method of injection and the technique of retronasal packing is discussed. Electrocoagulation may be necessary but Reeves does not often use that method.

When secondary bleeding occurs from the adenoid fossa an attempt should be made to find the cause. Several causes are mentioned. Control of this type of bleeding is similar to that mentioned but it is usually accomplished by removal of the clot and dropping adrenalin into the nose to reach the bleeding area. Supportive treatment is frequently necessary as is the use of drugs to increase the clotting of the blood.

NECK

Lerman, J., Jones, H. W. and Calkins, E.: Studies on 2 Sporadic Cretinous Brothers with Goiter together with Some Remarks on the Relation of Hyperplasia to Neoplasia. *Ann. Int. M.* 1946 35 677.

The results of studies made on 2 cretinous brothers are presented in detail, along with brief clinical histories. The records of 2 other cretins with goiter seen previously were re-examined. The relationship between hyperplasia and neoplasia is discussed. Experimental findings in cases in which thyroid carcinoma was produced by thiouracil in the treatment of hyperthyroidism are considered. It was suggested that thiouracil be used only as a preliminary medication in preparing the patient for thyroidectomy.

RICHARD J. BENNETT, JR., M.D.

Beierwaltes, W. H., and Sturgis, C. C.: Complications following the Administration of Thiouracil. *Am. J. M. Sc.*, 1946 212 513.

The author after reviewing 7 fatalities from agranulocytosis following the administration of thiouracil, concludes that the most effective therapy for

this condition is the early administration of penicillin. Also the symptoms of fever malaise or sore throat occurring in a patient under treatment with thiouracil if properly evaluated will lead to earlier recognition of the agranulocytosis and earlier stoppage of the offending drug. The author also concludes that thiouracil should be stopped when the white blood cell count drops below 2000 per cubic millimeter.

A series of 80 patients was treated with thiouracil. Five patients (6 per cent of the group) developed neutropenic leucopenia or agranulocytosis. The author believes that often in cases of neutropenic leucopenia after temporary stopping of the thiouracil it may again be administered with satisfactory results. However 1 of the 2 patients in this series that developed agranulocytosis developed a recurrence when the drug was resumed. There were no fatalities from agranulocytosis in this series. In only 1 of the 80 patients was it necessary to discontinue thiouracil because of a febrile reaction. In 2 of the 80 patients the results of thiouracil therapy were thought to be only moderately successful and thyroidectomy was performed. This was done in spite of the fact that the basal metabolic rate was reduced to within normal limits in both cases. Because of the incidence of carcinoma in patients with nodular goiter thiouracil is used only as a preoperative measure in these cases. In the 1 case of dermatitis which appeared in this series the drug was successfully readministered following the disappearance of the rash. Leg edema and jaundice were not observed in this series.

The author does not believe that there is a higher incidence of progressive exophthalmos in patients treated with thiouracil than in those in whom a thyroidectomy is performed. He now uses thiouracil plus desiccated thyroid to treat malignant exophthalmos. He believes that thiouracil is superior to iodine for preoperative preparation of patients with hyperthyroidism.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Lysholm E.: Experiences in Ventriculography of Tumors below the Tentorium *B u J Radiol* 1946, 19 437

This memorial lecture was delivered in April 1946 to honor Mackenzie Davidson the well known British radiologist. The subject matter has to do with

467 Infratentorial lesions examined by ventriculography from 1930 to 1946. One hundred and four cases had previously been discussed in an article published in 1935 to which the author refers us in regard to his technique. This technique has not changed in any essential detail neither laminography nor terroscopy are used for it has always been possible to visualize the aqueduct and the third and fourth ventricles. The anatomy of the structures to

Fig. 2 Left, Drawing of typical hemisphere tumor showing displacement of aqueduct and fourth ventricle (frontal) right, frontal roentgenogram of hemisphere abscess. Right hemisphere expanding process (verified abscess). Moderate symmetrical hydrocephalus. Kink in middle of aqueduct. Fourth ventricle and aqueduct displaced forward and slightly to the left.

Fig. 3 Left, Frontal roentgenogram. Lateral displacement of aqueduct and fourth ventricle; right, lateral roentgenogram of same case. Cerebellopontine angle glioma (medulloblastoma verified). Symmetrical moderate hydrocephalus. Aqueduct and fourth ventricle displaced to the right. Aqueduct displaced somewhat backward. At operation the tumor was found in the right cerebellopontine angle growing in the pons and right cerebellar hemisphere.

TABLE I — VERIFIED CASES OF INFRATENTORIAL LESIONS INVESTIGATED BY VENTRICULOGRAPHY FROM 1930 TO 1946

	No. of cases
Expanding lesions in the posterior part of the third ventricle (mostly pinealomas)	63
Aqueduct stenosis	63
Corpora quadrigemina	23
Pons region	24
Cerebello-pontine angle (21 of these = acoustic tumors)	36
Vermis and fourth ventricle, above fastigium	77
Vermis and fourth ventricle, below fastigium	110
Cerebellar hemispheres	100
Arachnoiditis	35
Total infratentorial lesions	467
Borderline cases between the medulla and cord	3

be examined is stressed and three projections, in different planes, are taken in any one position of the head.

The presentation is really a series of 56 pictures of pathological specimens, special views of the head with air or oxygen in the ventricular systems, and diagrams. Table I is descriptive of the material that forms the basis of the demonstration.

Although the series shows great accuracy in the localization of tumors below the tentorium, it was

pointed out that this method must be used in conjunction with careful general and neurological examinations. Certain errors managed to creep in. For instance, there were 42 negative ventriculographies for suspected expanding lesions of the posterior fossa of which 36 were never explored. Of the remaining 6 cases, 5 were explored with the following verified results: 1 stem tumor 2 meningiomas 1 acoustic tumor and 1 fourth ventricle tumor. The sixth case was diagnosed clinically as a pons tumor and x ray treatment was given. The patient died 3 months later but an autopsy was not obtained.

ADRIEN VAN BRUGHEM, M.D.

Cramer, F. J.: *Surgical Treatment of Syringobulbia and Syringomyelia*; Report of 2 Cases. *Arch. Neurol. Psychiat.*, Chic. 1946, 56, 443.

The author has presented 3 cases of syringobulbia and syringomyelia which were treated surgically with the belief that they are the first so reported in the literature. The indications for operation in cases of these disorders were listed as being identical with those for syringomyelia, namely rapid progression of the symptoms, increase of the intracranial pressure, cerebrospinal fluid block and accurate neurological localization.

Syringomyelic types of lesions have been known to occur with the Arnold-Chiari syndrome. The author observed in the first case that the cerebellar tonsils were herniated into the spinal canal but since this area was not explored it was impossible to say

whether the tonsils were attached to the cord. However the fact that the medulla and the fourth ventricle were in their usual position without any traction exerted upon them, and the fact that there were no bony defects found in the skull indicated that the cavitation did not result from an extra-axial cause.

Likewise it has been reported by other observers that arachnoidal adhesions have occurred in certain cases of Arnold-Chiari deformity with associated underlying syringomyelic lesions. The author stated that in spite of the fact that there was a thickening of the arachnoid membrane with vascularization of the syrinx there was no possible etiological relationship between the two for the cyst was primarily in the medulla and the adhesions were atlanto-occipital. Adhesions can be regarded as a causative factor only when they are bandlike and constricting in character.

The pathological process involved in syringomyelia and the associated conditions was discussed. These congenital anomalies are developed from ectopic glial cells which undergo both growth and degeneration. Symptoms are produced (1) by direct involvement of the cranial nerve nuclei and the fiber tracts, (2) by disturbance of the vascular supply to normal neural tissue and (3) by direct increased pressure of the fluid and degenerated products within the syrinx upon the surrounding tissues.

The problem of obliterating the cavity or maintaining the communication between it and the subarachnoid space was considered. It was the opinion of the author that the production of fluid within the syrinx is on the basis of degeneration of abnormal cells and not due to the secretion of new material. The final stages of this destruction of tissue was regarded as being present in most cases which required operation and it was believed that recurrence of the cyst would not take place at the point where operation had been performed.

Postoperatively the 3 patients whose cases were presented showed a definite relief of increased intracranial pressure and no further advance of the pathological process 14 and 18 months after operation respectively. On the contrary the second case even had some regression of symptoms because the signs were on the basis of edema, which subsided and the patient was able to return to work. These factors suggest that operation should be undertaken in these conditions when the above mentioned criteria for operation are noted. RICHARD C. SCHWEIDER, M.D.

Van Wageningen, W. P.: Observations on Changes in States of Mental Depression and Tension following Surgical Section of Certain Frontal Lobe Pathways. *Surgery* 94, 30 656

The author reports 4 cases in which various surgical sections have been undertaken in the treatment of severe mental depression.

The first case was that of a male with mental depression sufficient to incapacitate him for work. A bilateral prefrontal lobotomy as described by Free man and Watts was performed and a satisfactory result was obtained. The patient returned to work

The second patient a sister of the first patient, also with marked mental depression, was treated first by preliminary burr holes over the coronal sutures on both sides and opening of the dura however no section of the white matter was carried out, and the patient's condition remained unchanged. Nine days later through an osteoplastic flap, the anterior portion of the corpus callosum was divided as well as the anterior commissure and the right limb of the fornix. An incision was made into the white matter anterior to the caudate nucleus on both sides and an estimated area of from 1 inch to 1½ inches square was sectioned. A completely satisfactory result was obtained following this procedure.

The third patient a male aged 44 also with severe mental depression and ideas of persecution, was operated upon with essentially the same procedure as that described in case 2. Again a satisfactory result was obtained.

The fourth patient a female aged 50, with extreme nervousness and emotional instability and depression was treated by a left prefrontal lobotomy (Watts technique). No essential change in her mental state resulted. Three weeks later the anterior half of the corpus callosum was divided, and a section of the right prefrontal white fibers anterior to the caudate nucleus was planned but could not be carried out because of technical difficulties. The patient showed only slight improvement in mood there was no other change.

The author believes that the results obtained in these cases support the belief that bilateral division of the white fiber pathways between the basal ganglia and the frontal lobe cortex is sufficient to secure relief from states of mental depression and tension. Section of more white fibers may be unnecessary. He also points out that prefrontal lobotomy, as described by Watts is a more practical procedure and is attended by less surgery and considerably less risk than the section described. He concludes that division of the white fibers in the corpus callosum is not followed by any change in states of mental depression or tension. HOWARD A. BROWN, M.D.

Horvath, G.: Experiences with Cortical Excisions for the Relief of Intractable Pain in the Extremities. *Surgery* 1946, 30 393

The author reports the cases of 4 patients with intractable pain in the extremities, who were treated by excision of the postcentral sensory cortex.

The first patient had had both arms amputated above the wrists, and in this case bilateral excision of the sensory cortex was done in two stages. Temporary relief of pain resulted following each excision, but the pain factors began to return at the end of a week, and within 3 weeks the pain was as severe as it had been before operation.

The second patient suffered intractable pain in the right hand and arm. The pain was thought to be due to some pathological condition involving the cervical roots, which had failed to respond to two laminectomies. Excision of the postcentral sensory

cortex resulted in very little temporary benefit but the patient was addicted to morphine which presented an added problem. The author considered this case also essentially a failure.

The third case was that of a patient with intractable pain involving the right arm and leg secondary to a deep-seated tumor. Removal of the tumor and x-ray therapy gave relief for a time. Upon the return of pain excision of the sensory cortex was done with relief of the pain although with considerable increase in motor disturbance and transient aphasia. The pain returned in the arm area after 5 months, although the leg and foot were still comfortable.

The fourth patient had severe pain in the right hand and arm secondary to a tumor which had been previously removed in part. Following excision of the sensory cortex, there was paralysis of the arm and weakness of the leg but relief from pain was had for almost a year at which time the patient succumbed as a result of the tumor and a pontine hemorrhage.

In each case the sensory area was mapped out by electrical stimulation and the author reported that by j out of 4 patients pain could be reproduced by stimulation of the cortical sensory areas.

The first 2 cases were considered failures, while the results in the last 2 were considered relatively successful.

Norden A. Peripheral Injuries to the Spinal Accessory Nerve. *Ida chir scand* 1946 94 515

A review of 16 cases of peripheral injury to the spinal accessory nerve calls attention to an apparently completely overlooked condition of incapacity, pain and weakness in the involved arm and shoulder.

Both the sternomastoid and trapezius muscles are doubly innervated the former by the second and third cervical and the latter by the third and fourth cervical nerves, as well as by the spinal accessory nerve. The anatomical course of the eleventh nerve is noted and its susceptibility to injury is pointed out—in cases of surgical intervention for the removal of tuberculous lymphomas, in hipspices, in direct contact with blunt instruments, and in trauma from gunshot wounds.

The symptoms consist of a feeling of heaviness in the arm, inability to lift the shoulder and pains of a dull aching type originating in the shoulder and radiating down the medial border of the scapula into the arm. The latter may be present on either the radial or ulnar side of the arm.

In 7 cases there were paresthesias in the form of numbness, prickling or throbbing sensations in the shoulder, arm or hand. On exertion, both pain and paresthesias in the extremity were increased in all cases.

Objectively there is paresis of the sternomastoid and trapezius muscles with associated atrophy. In the case of the latter muscle, this is not complete because of the double innervation of the muscle. Re-

flexes of the arm are normal and in no case is variation of the radial pulse noted. However, only 6 of the cases were observed for this factor.

Pains are of two varieties: (1) those due to depression of the shoulder with tension on the brachial plexus which tend to disappear upon supporting the extremity (apparently no part of the plexus is routinely involved because numbness may be present in part or all of the extremity) and (2) those due to periarthritis and peritendinitis secondary to disuse of the extremity.

Two of the 16 patients were without any pain but had pronounced paresis the remainder a majority of the patients, had pain in varying degrees, which more or less interfered with their ability to earn a livelihood.

The most satisfactory method of treatment, of course is prophylaxis. For operations in this area, it is believed that the spinal accessory nerve should first be sought and identified before any tissue is excised. A less risky zone should be selected for biopsy and if this is not possible the procedure should be carried out on the left side of the neck in right hand individuals where bilateral nerves are available. In cases of paralysis of the seventh nerve, in which anatomous operations are necessary it is suggested that the twelfth nerve be used instead of the spinal accessory nerve thereby causing less discomfort to the patient.

Once the injury has been sustained active treatment consists in suture of the nerve within 2 to 3 weeks. Orthopedic bandages have been suggested, but are believed to be unsatisfactory. Muscle and fascial plastic procedures are of avail in some cases for support of the scapula. X-ray therapy and exercise are advocated for associated periarthritis and peritendinitis.

Richard C. Schroeder, M.D.

SPINAL CORD AND ITS COVERINGS

Fincher E. F.: The Differential Diagnosis of Intervertebral Cartilage Ruptures and Intraspinal Tumors within the Lumbar Sacral Canal. *Seix's Surg* 1945 12 393

The increasing notoriety and popularity of the ruptured disc' has served to focus diagnostic attention on the fact that radiating nerve root pain is more likely to be of mechanical origin than the result of so-called inflammatory or other intracanal changes in the nerve structures. The 'disc' possibility as a cause for a lumbago-sciatica syndrome has had its influence in bringing about earlier recognition of these two groups is by no means always easy. In the fulblown late developments of spinal cord compression the diagnosis is not difficult and can be accurately made from a neurological examination. With the history of a specific initiating low back trauma and a subsequent radiating low back pain is quite likely the accurate diagnosis, but such symptoms may indicate an intraspinal tumor within the lumbar spinal canal.

In a large series of patients with clinically diagnosed ruptured lumbar intervertebral cartilages, who were incapacitated by their sciatic pain which conservative treatment had failed to relieve it was found that approximately 1 per cent of the group had intraspinal tumors. It was learned further from a study of clinically diagnosed tumors, that a higher percentage had completely herniated (either a full annulus or a nucleus pulposus, or both into the lumbar spinal canal) to produce a complete obstruction. These two groups, (1) the tumors diagnosed as discs and (2) the discs suspected as being tumors, form the basis of the present communication.

The subjective symptoms of these two groups of patients may serve to be very misleading in the clinical diagnosis. The history of trauma may be elicited in approximately 85 per cent of the cases of intervertebral disc.

In about one-third of the cases a history of exacerbations and remissions of symptoms was obtained. The remission of symptoms usually following bed rest. In the cases of intraspinal tumors there was no frank evidence that prolonged bed rest of the patients contributed to the alleviation of nerve root pain. The author points out that a general clinical rule might be that "disc patients lie and tumor patients walk" for relief of their nerve root pressure symptoms.

Intensification of sciatic pain on coughing and sneezing has been stressed as an important clinical sign of a ruptured disc. Occasionally this is true of tumor patients. Activities that entail low back bending are more likely to intensify the symptoms of ruptured disc, than those of tumors. In the case of ruptured discs, there is a tendency for a "list" to the non painful side. Subjective motor handicaps are infrequent in both tumors and ruptured discs. An acute complete rupture of a disc may precipitate a frank paralysis of dorsiflexion of the feet. A footdrop in a tumor patient develops instantly and is rather a latent manifestation of nerve root damage. Patients with ruptured disc are more prone to notice calf atrophy than are patients with tumor. In general, parasthesias of a ruptured disc are referable to one lower extremity whereas, in cases of tumor they are referable to both lower extremities. Muscle spasm of the lumbar erector group is strikingly absent in cases of tumor and a rather constant finding in cases of ruptured disc.

The author discusses the investigative procedures which are roentgenography of the lumbosacral vertebra, spinal puncture with manometric determination and fluid studies, and occasionally contrast media visualization of the spinal canal. He states that there is no necessity to make these procedures a routine in clear-cut cases of ruptured disc, but they are used when necessary for the making of a differential diagnosis. He also calls attention to the use of the exploratory operation for cases in which the diagnosis is in question. As a general rule, this is also a therapeutic procedure.

PAUL MIRANDA, M.D.

PERIPHERAL NERVES

D Aubigné, R. M.: The Treatment of Loss of Substance in Nerves (A propos du traitement des pertes de substance nerveuse) *Mém Acad. chir. Par.* 1946 73 409.

Since October 1945 100 peripheral nerve lesions, of which 59 had loss of substance, were treated at a surgical center. Because nerve grafts were considered unsatisfactory every effort was made to obtain end-to-end suture and it was found that unexpectedly large gaps could be closed for instance 10 cm. in the median nerve 10 cm. in the ulnar 8 cm. in the radial, 10 cm. in the sciatic and 7 cm. in the common peroneal nerve. It is true that these long distances were covered in only single cases except in the instance of the radial nerve in which it was possible to gain 8 cm. on 2 occasions. Every available method was used to obtain closure of the gap including extensive mobilization of the nerve, transposition of the nerve flexion of the joints, and in 4 cases, shortening of the long bones. Only 30 cases could be followed up and among these there were 12 regenerations and 8 failures. As would be expected the length of the gap that must be bridged bears some relation to the result. In 5 cases in which the gap was 4 cm. or under there were 5 cures, but when the distance was over 4 cm. the results deteriorated by 50 per cent. The following table is a summary

TABLE 1.—LENGTH OF LOSS OF SUBSTANCE

	Cure	Failure
Less than 4 cm	5	0
4 to 6 cm.	3	1
6 to 8 cm.	2	3
8 to 10 cm.		2
over 10 cm	1	—
	23	8

In some cases a graft has to be used, and on experimental grounds the autograft should be the most useful. This was proved to be the case clinically. The author's results with autografts and auto-cable grafts are not given. ANDREW VAN BUREN, M.D.

D Aubigné, R. M.: The Treatment of Loss of Substance of the Peripheral Nerves (Traitement des pertes de substance des nerfs périphériques) *J. chir. Par.* 1946, 62 391.

The ideal goal of all treatment of loss of substance of the peripheral nerves is the complete restoration of the function which had been interrupted by the trauma. This can be reached only if the axons growing from the central stump are permitted to enter into the Schwann tubes of the peripheral stump and to reach their sensitive or motor end-organs.

If it is ever possible the direct end-to-end suture is preferable to grafting. Even if there is a considerable gap between the two ends, they can be approximated by different procedures.

1. Dissection of the nerve to a great length. By this technique alone from 5 to 6 cm. of length can be

gained in dissection of the median nerve. It is true that by very extensive dissection the vascularization of the nerve and consequently its function and regeneration may be jeopardized however experience shows that because of a network of intraneural anastomoses the resistance of the nerve to ischemia is remarkable. In any case a dissected nerve will be always better vascularized than a graft.

2. Further length can be won by transposition i.e., by changing the normal course of the nerve. This is true particularly for the ulnar nerve. Here the transposition of the nerve anterior to the epicondyle combined with flexion of the elbow permits end-to-end suture even in losses of up to 10 cm of nerve substance.

3. Additional length can be gained by appropriate position of the limbs. In the upper extremity adduction of the shoulder and flexion of the elbow permit repair in lesions of the median, radial and ulnar nerves.

4. Suture in two stages has been suggested when approximation is impossible with the afore described methods however the results are not satisfactory and the method has been given up by the majority of French and British surgeons.

These mechanical devices for lengthening the nerve make end-to-end suture possible if the loss of nerve substance does not exceed 12 cm. in the sciatic radial nerve and 10 cm. in the popliteal nerve. If none of these methods is applicable there is finally the possibility of shortening the limb by resection of the bones. The applicability of this heroic method is, however quite limited it is justified only for the humerus if there is delay in union of the fractured bone in addition to the nerve injury.

The suture should not be made immediately after the injury. Statistical papers as well as histological examinations have proved definitely that the early secondary suture is much superior to the primary suture. The best time for the intervention is between the nineteenth and twenty fifth days after the injury this being the period of maximal proliferation of the Schwann cells.

If direct suture is definitely impossible, grafting is indicated. Three kinds of graft are possible: heterografts i.e. replacement by animal nerves (dog cat rabbit), homografts in which nerves from the amputated limbs of other patients are used and finally autografts in which cutaneous nerves of the patient are transplanted to the injured nerve. The results of the heterograft method have been rather disappointing and it has been condemned practically unanimously by American and British authors. In contradistinction to this negative attitude European authors report partial or complete regeneration in about 30 per cent of the cases. It seems to be important that the grafted nerve is living tissue (fresh dog nerve). In any case the heterograft should be reserved for cases in which no other method is possible.

The results of the homograft method have been equally disappointing as the transplanted nerve usually becomes necrotic and is replaced by bands of fibrous tissue.

The results of the autograft method have been much more encouraging. French, as well as American, authors reported success with autografts of the radial and median nerves up to a length of 15 cm. Here the main problem is to find a sufficient amount of material for the transplantation without causing functional damage. In most cases the internal cutaneous brachial or the external saphenous nerves are employed. As these nerves are of small diameter they have to be tripled or quadrupled to replace loss of substance in larger nerves (cable technique). The smaller the diameter of the transplanted nerves the better is the prospect. Small nerves are supplied with nutrient by the environmental tissue whereas large nerves when grafted, necrotize in the center. As suture material either human hair or thread of tantalum seems to give the best results. The most difficult problem is presented by the sciatic nerve because of its large caliber.

It is essential to resect the stumps especially the distal one before suture or graft is made to make sure that the operation is performed in healthy tissue. Most failures are caused by insufficient excision of the sclerotic tissue at the distal stump. Some men prefer to glue the stumps together with plasma or to apply cuffs of metal or other material rather than to suture. In case of failure to restore the nerve function palliative treatment must be applied. Motor paralysis can be compensated for in many cases by tendon operations arthrodeses and arthrotomies.

WERNER M. SOLMITZ, M.D.

Wertheimer and Mathieult: Results of Surgical Treatment in Wounds of Peripheral Nerves with Loss of Substance (Résultats de la thérapeutique chirurgicale dans les plaies des nerfs périphériques avec perte de substance). *Mém. Acad. chir.*, Paris, 1946, 73-398.

This is the first group of cases reported by a French author concerning patients seen in the 1939-40 campaign and that of 1944-45 who received surgical treatment for wounds of the peripheral nerves with loss of substance. All patients were operated on under the direct supervision of one person and therefore present a group treated in a uniform manner. Follow up reports of some of the cases were unobtainable because of transfers in North Africa and return of the patients to their country. Some cases are too recent to be of value.

In all, 67 observations were made and a comparison was made between direct suture by mobilizing the nerve and flexing the joints over which it runs with immobilization and the results obtained by various forms of nerve grafts. The types of nerve grafts used were heterografts with the spinal cord of the rabbit or cat, 11 cases; autografts usually with the medial cutaneous nerve of the arm, 10 cases; and homografts from amputated limbs 9 cases. Only

TABLE I.—THE TIME FACTOR IN RESULTS

Immediate suture	Cases 100% successful
During the first month	3 Cases 33% successful
During the second and third month	7 Cases 43% successful
During the fourth and fifth month	1 Case 7% successful
During the sixth and seventh month	4 Cases 15% successful
From seven months to a year	8 Cases 0% successful
After a year	3 Cases 0% successful

1 autograft was a success and it was used on the ulnar nerve in the arm 25 months after operation the patient had only some weakness in the abductor digiti quinti. One other autograft and 2 homografts showed slight evidence of regeneration.

In direct suture of nerves, in contrast to nerve grafting the results depend on the wounding agent and the time of suture. For instance the same author states that in civil practice there were failures in 45 per cent of the cases whereas in military practice there were failures in 60 per cent.

ADRIEN VER BROECHEM, M.D.

MISCELLANEOUS

Van Rijssel T. G.: Circulation of the Cerebrospinal Fluid in *Carassius Gibelio*. *Arch. Nerv. Psychiat. Chic.*, 1946, 56: 522

Controversial opinions regarding the origin, movement, pathways, absorption and function of the cerebrospinal fluid are prevalent in the literature. To determine the extent of the perivascular spaces and circulation of the cerebrospinal fluid in these areas the following experiments were undertaken. A species of carp *Carassius gibelio*, was selected

because its anatomical features facilitated such a study. Eight fish were allowed to swim in solutions of trypan blue. Subsequent examination revealed that dye failed to enter the central nervous system. Thus, a blood-cerebrospinal fluid barrier exists for trypan blue.

To trace the flow of cerebrospinal fluid dye (trypan blue or India ink) was injected into the pericerebral spaces of these fish and microscopic examination of serial sections was made. The fish were killed at varying intervals of time following the injection. The significant facts revealed were:

1 Perivascular spaces occur in the brain of *Carassius gibelio* and these are in open communication with the meningeal spaces and the ventricles.

2 Particles of trypan blue or India ink pass through these routes from the meningeal or ventricular spaces into the perivascular spaces.

3 Movement within the perivascular spaces occurs in the same direction as that in which the blood flows and is attributed to the vessel pulsations.

4 An extensive interchange of cerebrospinal fluid takes place between the ventricular fluid or internal cerebrospinal fluid and the external fluid, or that surrounding the brain in the meshes and chambers of the meningeal tissues. This exchange occurs through the thin roof of the third ventricle and the perivascular spaces of the vessels reaching the surface of the brain from the ventricle.

5 The choroid plexus of the fourth ventricle absorbs colloidal suspended particles from the ventricular fluid.

6 There is a strong blood-cerebrospinal-fluid barrier and a less absolute cerebrospinal fluid-parenchymal barrier for trypan blue. The latter of these barriers is stronger with respect to India ink.

C. FARKHATZ KRITZ, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Aiken, D. Brodie's Disease of the Breast. *Brit J Surg.* 1946, 34: 87

Unusually large noncancerous breast tumors were recognized early in the nineteenth century. Brodie, in 1846 and his contemporary Cooper regarded the neoplasm as an advanced stage of cystic disease of the breast. Brodie's penetrating observations and gift of graphic description earned him the deserved honor of the eponym. There have been only 125 cases recorded to date in the medical literature.

The term "Brodie's tumor" should be reserved for large, excessively cellular and long neglected fibroadenomas. The history of a pre-existing breast tumor of many years' duration which at first grows slowly or not at all and, finally in late middle age increases rapidly in size is the outstanding feature of this tumor. Commencing as a fibroadenoma, it maintains the characteristics of an innocent lesion throughout. The skin overlying the tumor is mobile; there is no fixation to the deep structures and the lymph nodes are not usually involved, apart from the hyperplasia due to inflammatory changes. Enlargement may be so great that ulceration of the skin results from pressure necrosis and the foul fungating mass in a patient past middle life at once suggests a carcinoma. Sometimes the correct diagnosis of an innocent large tumor is impossible until the breast is removed. One striking clinical feature in typical cases is the excellent general condition of the patient.

Local recurrence following excision of the tumor has been reported on rare occasions, especially by the earlier writers, and convincing evidence of malignancy is even rarer.

The cut surface of a Brodie's tumor reveals an encapsulated mass showing white whorled areas, deep clefts, and translucent lobules, some of which degenerate into cysts. Microscopically its structure is that of an intracanalicular fibroadenoma which has become very cellular and shows degeneration and even cystic softening. In the cellular areas of the fibroblast dividing cells may be found but the mitoses are regular. It is this appearance which may lead to the diagnosis of sarcoma.

The best treatment of Brodie's tumor appears to be simple mastectomy rather than local excision for care must be taken not to leave any breast tissue behind in the skin flaps. It is possible that recurrence of the tumor may take place from a fragment remaining *in situ* as in simple tumors of the parotid gland. It has been suggested that the rapid growth of these fibroadenomas in late middle life may be associated with diminished estrogenic activity.

The author reports a case of a 68 year old woman who presented the described picture. A simple mastectomy was done. One year later there was no evidence of recurrence.

LEX PULLEN M.D.

Ragnell A.: Operative Correction of Hypertrophy and Ptosis of the Female Breast: 300 Cases. *Acta chir scand.* 1946, 94: Supp. 113.

Plastic surgical procedures for the correction of hypertrophy and ptosis of the female breast are presented in a complete and detailed monograph. The subject matter is presented in four parts and a comprehensive bibliography greatly enhances the value of the report. Results and criticisms of the author's methods, evolved over a series of 300 cases in the past 9 years, are forthrightly presented.

Part 1 is devoted to embryology, physiology and anatomy. The circulatory system of the breast, both blood and lymph, receives the greatest attention. From an analysis of the investigations of numerous anatomists, it appears that the individual breast may have a variable blood supply with the internal mammary and long thoracic arteries always present and the third to seventh intercostal arteries usually present, but supplying blood in a somewhat different degree. The areola and nipple usually form a splenic anastomosis from the first two arteries with the aid of the intercostal arteries in some instances. In some breasts, however, this area is supplied by end arteries, and as there is no way of determining such a condition in advance, due caution is always necessary. There are no universal laws for circulation in the mamilla. Nerve supply, lymph circulation and the physiology of lactation are discussed.

In part 2 a classification of breast deformities is attempted. The groupings of various authors are presented, and the author suggests the following classification, which he uses:

1. Bilateral overdeveloped breasts with and without ptosis.
2. Breasts of normal size with ptosis.
3. Bilateral underdeveloped breasts with and without ptosis.
4. Asymmetrical breasts over or under developed with and without ptosis.

Causative factors of the different types of breast deformity are discussed.

With regard to the indications and contraindications for plastic surgical procedures, consideration should be given to (1) the symptoms complained of by the patient (as often mental as physical) and (2) the skill and experience of the surgeon.

A thorough discussion, with excellent illustrations of the several more or less classical procedures of Passot, Blesenberger, Gilles-McIndoe, and Malinjak, and criticisms of each procedure follow. Once again great emphasis is placed on circulatory considerations. Loss of the nipple and areola is of course the paramount apprehension in reconstructive procedures of the breast. Practically all authors agree that venous stasis is the predominant cause of necrosis of the nipple. The innervation and lactation of breasts following surgery are briefly discussed.

Fig. 4 Method II (two stages) Stage I a, Skin incisions marked. b, Skin retracted, sector shaped resection from gland. c, Reconstruction of gland. d, Skin covering preparatory to reduction of lower skin flap. e, Final skin suture.

In part 3 the operative techniques used by the author and their evolution from the methods of others are presented. Preoperative and postoperative care are considered. The author uses both a single stage procedure in cases of breasts without enlargement or with only moderate hypertrophy and a two stage procedure for long and pendulous breasts and those with more marked hypertrophy.

In the final section the author criticizes his method as to its anatomical and clinical aspects. Tables pertaining to symptoms weights of resected tissues diagnosis complications etc. are presented and anatomical and physiological results are tabulated.

This monograph is worthy of study by anyone interested in plastic or reconstructive surgery on the female breast.

EARL H. KLABONET, M.D.

TRACHEA LUNGS, AND PLEURA

Geland, G.: Traumatic Pulmonary Edema Treated with Concentrated Plasma. *Lancet* Lond. 1946 1: 667

Pulmonary edema due to trauma carries a grave prognosis. It was observed frequently in battle casualties, and its causes included blast petrol explosions, chest wounds, fat embolism and accidental overtransfusions with either blood or saline solution. In civilian accidents it is observed in burns due to underground explosions, in petrol explosions, in accidental inhalation of noxious gases in industry, and in accidental overtransfusions. Pulmonary edema is characterized by severe respiratory distress and pronounced cyanosis. Large quantities of frothy mucus are thrown up into the trachea and well up through the larynx. According to the degree of consciousness present, attempts are made by the patient to cough up the frothy mucus. Auscultation of the chest detects coarse crepitations which sound very close to the stethoscope. Danger to life lies in drowning from vast quantities of mucus in the alveoli and bronchial tree.

The author states that he has observed on many occasions that concentrated plasma administered intravenously reduces edema in second degree burns apparently by its direct action in raising the osmotic pressure in the capillaries. If this can be done in traumatic edema in other parts of the body it should be possible in pulmonary edema due to trauma. The author outlines his method of treatment for pulmonary edema of traumatic origin.

1 Atropine (gr 1/50) is administered intravenously to diminish bronchial secretion to a minimum as soon as possible.

2 As much of the mucus in the bronchial tree as possible must be removed. This is accomplished by postural drainage, aspiration and injection of the drugs which tend to produce a temporary return of the cough reflex.

3 Oxygen is given continuously by a method which insures maximal concentration of that gas in the nasopharynx.

4. Concentrated plasma is administered intravenously. Originally double strength plasma was used later triple strength plasma has been used. The plasma is administered at a rate of 80 drops a minute, and little difficulty is experienced in maintaining the flow if slight pressure is used. A dose of 400 c.c. is usually adequate but occasionally up to 800 c.c. are required.

5 Other fluid intake is regulated to a minimum to obtain the maximal benefit from the increased protein concentration in the circulating blood.

The author gives 5 case reports in which this procedure was used and summarizes his article as follows.

Intravenous administration of concentrated plasma has seemed to be a valuable addition to recognized methods in the treatment of pulmonary edema due to trauma. Illustrative cases are described.

There has been no tendency for the pulmonary edema to recur after this treatment in the types of cases described. Apart from the risk of reactions to the plasma, the method is dangerous only if applied without preliminary venesection in cases of pulmonary edema due to overtransfusion.

PAUL MERRELL, M.D.

Brock, R. G.: Studies in Lung Abscess. *Guy's Hosp Rep* Lond. 1946 95 40.

Abscess of the lung due to infection with Friedlaender's bacillus is a rarity like staphylococcal lung abscesses, it serves as a characteristic example of an abscess due to a specific infection. This is in contrast to the much larger group in which the primary cause is some form of bronchial embolism. In the case of a Friedlaender's infection the primary event is a specific pneumonia and the abscess follows this pneumonia. The condition is indeed 'pneumonia with abscess formation'. The statement that lung abscess usually follows pneumonia is largely incorrect. In nearly 75 per cent of cases it is possible to identify the primary cause as other than a primary acute pneumonia.

The acute pneumonia caused by Friedländer's bacillus is notorious for its gravity and its high mortality. Usually the clinical course is short none of the earlier reports describes a chronic form of the disease. The scanty literature reveals that 18 cases have been reported in which the ordinary acute specific pneumonia caused by Friedländer's bacillus did not end fatally but broke down to form abscesses and assumed a chronic suppurative course. The condition in some of the patients resolved with fibrosis some patients ultimately succumbed.

The bacillus of Friedländer must always be thought of as the possible causal organism when abscess formation appears in a gravely ill patient. It most also be borne in mind if such a suppurative process becomes chronic, and particularly if the persistence of thin walled cavities with metastatic lesions elsewhere in the lung stimulates chronic pulmonary tuberculosis, but the sputum is consistently negative for tubercle bacilli.

Two additional cases are reported, which brings the total to 20. SARREL KARR M.D.

Paul, L. W., and Ritchie, G. Pulmonary Adenomatosis. *Radiology* 1946, 47: 354.

Pulmonary adenomatosis in man is a rare pulmonary disease characterized by the development of multiple nodular adenomatous tumors or by diffuse hyperplasia of the pulmonary alveolar lining. The disease is bilateral and lateres greatly with the gaseous exchange. Metastases do not occur elsewhere in the body and patients usually succumb from terminal pneumonia. Pathologists speculate on its close histological resemblance to an infectious disease of the lungs, called jaggiektie in sheep and other animals. This disease is endemic in many areas of the world. It is believed to be of infectious origin and possibly due to a virus. Just what relationship exists between jaggiektie and pulmonary adenomatosis in man remains to be determined.

Bonne in 1939 first described this condition in man and called attention to its close resemblance to jaggiektie in sheep. He suggested calling this condition carcinomas rather than carcinomas. Numerous cases of a similar nature have been recorded in the literature, but they vary chiefly in the bronchial metastases have been found either in the bronchial lymph nodes or scattered widespread throughout the body. The disease has been referred to as alveolar cell carcinoma and shows the characteristics of a malignancy. The metastases often influence the clinical symptoms and progress to a considerable degree.

The authors limit their discussion to cases in which metastases do not occur and which resemble more closely Bonne's original description.

Investigations to determine the infectiousness and the presence of a virus in pulmonary adenomatosis are few and thus far have been fruitless.

The pathological lesion consists typically of scattered nodules of consolidation on the cut surfaces of

the lungs. These are usually mistaken for patches of gray pneumonia until microscopicly they are identified as localized occurrences of abnormal lining to the alveoli. The lining is made up of either low or moderately high cuboidal epithelium, the cells of which tend to be slightly pear shaped and form papillary projections into the alveolar spaces. These cells are believed by some to have arisen from alveolar covering cells although there is some evidence that they come from bronchial epithelium. The alveolar walls in these nodules are thickened and edematous, with increased connective tissue.

The authors present 5 cases of pulmonary adenomatosis, illustrated by x-rays and photomicrographs. A study of the histology in these cases seems to show (1) that the abnormal epithelium of adenomatosis is derived in some cases at least, from bronchial epithelium and (2) that in certain cases adenomatosis constitutes a transitional form between normal lung and carcinoma and must be regarded as a potentially precancerous lesion.

The onset of pulmonary adenomatosis is usually insidious, although in several of the authors' cases it was accompanied by symptoms of an acute respiratory infection. Dyspnea and cough were the most common symptoms. The dyspnea is due to r placement of the alveolar cell lining with abnormal cells, which interferes with gaseous exchange. Tercious secretions in the alveoli and bronchi also cause dyspnea. The dyspnea may be far out of proportion to the extent of the pulmonary involvement that can be demonstrated roentgenographically.

The cough is usually productive of thin, watery frothy mucoid sputum. The sputum may be abundant early or late in the disease. Hemoptysis does not occur in a terminal phase. This watery sputum is only in a terminal phase. This watery sputum is only in a terminal phase. This watery sputum is only in a terminal phase.

be accounted for by the tendency of the alveolar cells to produce mucin.

The remaining symptoms of weight and strength loss, fever and anorexia are not of diagnostic importance. In the majority of cases the condition occurs at the usual age period for carcinoma. The duration of the disease is for months or years, 4 months, and a year, respectively.

A review of roentgenograms shows a main type of lesion neither of which is in any way characteristic. One group of lesions is manifested by an area of consolidation which is in any way characteristic. Another group of lesions is manifested by an area of consolidation which is in any way characteristic. Another group of lesions is manifested by an area of consolidation which is in any way characteristic.

The diagnosis is purely of academic interest since all cases of the disease have been fatal. The possibility of lobectomy or pneumonectomy has been suggested if the disease can be recognized early enough before it has spread widely.

It is hoped that with the accumulation of additional cases in the future a better understanding of the clinical and roentgen aspects of the disease may be obtained.

ROBERT R. BIRLOW M.D.

Mastakallio, S. The Result of Roentgen Therapy in Histologically Verified Cases of Pulmonary Cancer. *Ann. med. int. fenn.* 1946 35 109

This investigation is based on 51 histologically verified cases of pulmonary cancer. The patients included 47 men and 4 women. The cases were divided into two groups according to treatment. The first included those who were given radical roentgen therapy (over 10 000 r on the skin) and the second, those who were not treated or who were treated insufficiently (under 10 000 r on the skin). The patients in the former group have lived on an average of 1 year 2 months, and 11 days after the beginning of the treatment and 1 year and 9 months after the onset of symptoms. Two patients are still alive and well one after 6 years and 10 months and the other after 3 years and 7 months following treatment. Metastases were found in the clavicular region and in the neck of the former patient. These metastases were treated and cured. This shows that in some cases cure can be obtained with roentgen rays but not with surgical treatment.

In the group of untreated patients the average survival time after diagnosis is 3 months and 5 days and from onset of the symptoms, 5 months and 9 days. The inflammatory processes around the carcinomas in the lungs have a disturbing effect on the roentgen treatment. Chiefly because of that fact only 21 of 51 patients have tolerated the radical roentgen therapy.

Roentgen treatment must be tried in all cases of pulmonary cancer if the general condition of the patient permits the trial of this very often strenuous therapy. If the patient tolerates this treatment, it must be continued until the tumor dosage of 6 000 r is reached.

JOHN E. KIRKPATRICK, M.D.

HEART AND PERICARDIUM

Welln, S., Hamberger, C. A. and Crafoord, G.: Surgically Removed Foreign Body Embolus in the Pulmonary Artery. *J. Thorac. Surg.* 1946 15 302

In this case reported by the authors a metallic object 1 cm in length over 1 mm. in thickness and from 7 to 8 mm in breadth had entered the femoral vein and had been thrown by the blood stream into the pulmonary artery.

There is no mention in the medical literature of a case in which a foreign body had entered a vessel so far toward the periphery as in this instance. From a diagnostic viewpoint this case was of the greatest

interest. Only by the combined use of the x rays and bronchoscopy could the exact diagnosis be made.

So far as the authors were aware, this was the first case in which the diagnosis of foreign body embolus in the pulmonary artery had been made prior to operation and in which the foreign body had afterward been extracted by thoracotomy plus arteriotomy followed by vascular suture.

The case report and operative procedure are given in detail.

JOHN J. MALONEY M.D.

ESOPHAGUS AND MEDIASTINUM

Morton, D. R. and Brunschwig, A. Peptic Ulcer of the Esophagus. Report of a Patient with 10 Year Follow Up. *Gastroenterology* 1946 7 314

The purpose of this report is to record the history of a patient seen in 1935 with a lesion which was at first thought to be malignant but which eventually proved to be a benign ulcer. The patient has subsisted principally by gastrostomy feedings until the

Fig. 1 (Morton and Brunschwig) Roentgenogram taken in 1935 showing constriction and deformity of lower thoracic esophagus which gave clinical impression of carcinoma.

Fig. 1. Photomicrograph (X50) of biopsy of esophageal ulceration secured in 1935 typical appearance of peptic ulceration.

present time (1945) a period of 10 years. When first observed in 1935 the question of resection was not seriously considered inasmuch as the technique for such a procedure had not been well defined and few attempts at such excision had been made. The patient, a 65 year old widow entered the Medical Service of Billings Hospital for the first time on June 16 1935 with the following story

One year prior to admission she noted burning epigastric pain an hour postprandially. Her local physician made a diagnosis of duodenal ulcer without the aid of x rays or gastric analysis. She was treated with powders and a bland diet and obtained complete relief. There was a weight gain of 3 pounds on this regime.

Two months prior to admission she began to vomit recently ingested food. At first this occurred 3 or 4 times a week. The vomitus was not bitter and contained no evidence of blood. The vomiting progressively became more severe. It occurred after every meal and began to be associated with sharp substernal pain which frequently radiated through to the back at a point between the shoulder blades. This pain was also noted upon swallowing food.

The patient stated "it felt as though there were an obstruction." At first, solids could be ingested, and then only fluids and finally during the 3 weeks before entry nothing could be retained. There was a weight loss of 45 pounds.

On physical examination she appeared emaciated and dehydrated and there was obvious evidence of recent weight loss. There were no remarkable findings pertaining to her condition other than changes associated with senility. The abdomen was scaphoid, not tender and presented no masses. Laboratory data were all within normal limits.

A provisional diagnosis of carcinoma of the terminal esophagus was made. The patient received parenteral fluids and roentgenographic study revealed that the esophagus was narrowed to approximately 3 or 4 mm for a distance of 9 or 10 cm. at the level of the seventh thoracic vertebra. The margins of the constricted area were somewhat irregular (Fig. 14). The mucosal folds were not completely destroyed and the segment of narrowing tended to change shape. Small peristaltic waves were seen passing through this area. There was no evidence of a "beak" or protrusion suggestive of ulcer or diverticulum. The mucosal pattern of the stomach appeared normal. It was decided to repeat the procedure described after the patient had inhaled amyl nitrite. Following this, there being no change the radiologist believed that the stricture was an organic lesion probably scirrhous carcinoma.

The patient was transferred to the surgical service with a preoperative diagnosis of carcinoma of the terminal esophagus. On July 2 1935 under local and ethylene anesthesia a high midline abdominal incision was made. There was no evidence of carcinoma within the abdominal cavity. The gall bladder wall was thick and contained many stones. The operative procedure consisted of a cholecystectomy and a Pezzer catheter gastrostomy (Brunschwig). The postoperative course was uneventful. Within 10 days she was tolerating a full gastrostomy diet, gaining weight, and appearing cheerful.

Esophagoscopy with biopsy was performed on 3 occasions, July 21 1935 November 11 1935 and December 16 1935. All 3 examinations revealed a narrowing to 4 mm. of the midportion of the esophagus. The right lateral wall was pale flat and showed an ulceration with well demarcated borders. The surrounding mucosa was red and granular. The granulations bled easily and the lumen was dilated. All esophagoscopic examinations gave the impression of carcinoma, but the 3 biopsies revealed chronic ulceration (Fig. 2). On none of the biopsy specimens was there epithelial lining.

The patient was discharged and followed up in the out patient clinic. Other than having to return every 6 to 8 months for replacement of the Pezzer catheter gastrostomy which became eroded from the gastric juice the patient enjoyed excellent health. She gained 30 pounds in weight on the gastrostomy diet, and gradually was able to take a pint of milk and a soft boiled egg by mouth each

day. However the main part of her nourishment was taken through the gastrostomy catheter. Roentgenographic study was repeated on November 16, 1937 and the stricture was found to occlude the esophageal lumen almost completely.

In 1939 she moved away from the vicinity of Chicago and was not heard from until she was readmitted to Billings Hospital on November 29, 1945. She was now 75 years of age and had been well until the previous June at which time she developed intermittent attacks of vomiting. The first attack continued for 3 days and the vomitus contained brown digested blood according to her physician. Roentgenological studies performed elsewhere were said to show advanced carcinoma of the terminal esophagus and the pylorus. She was advised to return to her original physician for treatment. Physical examination revealed an elderly female in comparatively good health. There were no findings of significance other than a slight excoriation of the skin about the gastrostomy tube which because of erosion was spilling gastric juice about its entrance into the abdomen.

The catheter was replaced under general anesthesia. Repeat roentgenographic studies (Fig 1B) revealed no change in the esophageal lesion except irregularity of the lumen in the constricted segment a crater 3 mm. in diameter was found in the duodenal bulb. There was no associated obstruction in this area.

Esophagoscopy revealed that the esophagus was normal to within 2 cm. of the constricted area. The posterior wall at this point was red. Anteriorly there was a tough rim (fibrous) which narrowed the lumen and prevented passage of the instrument. The No. 15 and No. 20 bougies were passed the former without resistance.

She was allowed no feeding by mouth, no phenobarbital and no tincture of belladonna. Gradually she was placed on milk and cream by gastrostomy catheter and she showed improvement rapidly. She was discharged on December 21, 1945 in good general condition.

The active duodenal ulcer might be associated with the presence of the Pezzer catheter in the stomach for 10 years although this is not certain.

Since resection of the esophagus entails much risk, the diagnosis of carcinoma should be confirmed by biopsy in any questionable case before such a procedure is attempted. The relatively satisfactory course in the case described even though subsistence by gastrostomy was necessary supplies information as to the course of the disease in cases of severe peptic ulceration of the esophagus. Possibly more efficient medical management might have alleviated the degree of stenosis that occurred.

JOHN J. MALONEY, M.D.

Lewis, I: *The Surgical Treatment of Carcinoma of the Esophagus*. *Brill J Surg* 1946 34 18.

The esophagus is a difficult surgical field for three reasons—its inaccessibility, its lack of a serous coat

and its enclosure in structures in which infection is especially dangerous and rapid. In the case of carcinoma of this viscus surgery is still more difficult for several reasons. It involves an extensive resection in a part of the alimentary canal which not only has no serous covering but also has no slack. It threatens the surgeon with having both pleurae open during the operation. Because of the loosely knit muscle anastomosis of its walls has with some reason been described as suturing the unsuturable.

It seems that in radiation therapy of the esophagus for carcinoma the upper third of this organ is occasionally cured in the middle third the growths are frequently of a radiosensitive type but they cannot be effectively treated because of their depth while in the lower third the adenocarcinomas are both relatively inaccessible and relatively insensitive. The author believes that direct irradiation of an inoperable growth through the operative wound combined with lateral anastomosis (esophagogastrostomy) is a treatment well worth trying.

The aims of radical cancer surgery are (1) to cure the disease while (2) rendering the patient's life useful and enjoyable or at least bearable.

Judged by this criteria the present position with reference to carcinoma of the lower part is very satisfactory. Not only does the resection with esophagogastrostomy satisfy the postulates of Halstead for the removal of cancer, but it also produces the best possible alleviation of symptoms. For growths of the lower part of the esophagus the left thorax is freely opened through the bed of the eighth rib. The phrenic nerve is paralyzed. The esophagus is mobilized and the diaphragm freely slit from the hiatus outward. The upper half of the stomach is mobilized and brought up into the pleural cavity.

The following are essential:

1. Adequate resection en bloc.
2. Removal of all tension from the suture line.
3. Avoidance of the least soiling.
4. An anastomosis which is end-to-side, two-layered, precisely stitched with interrupted sutures.
5. Just as the sheet anchor in abdominal anastomoses is the serous coat in the esophageal anastomosis it is the mucosa. This is thick and comparatively strong.
6. Water sealed drainage and early expansion of the lung.

For growths of the midesophagus also most surgeons have used the left transpleural approach. However the advantages of the right transpleural approach are:

1. A far better accessibility of the upper two-thirds of the thoracic esophagus.
2. Only the vena azygos major has to be divided to lay bare its whole course.
3. The aortic arch (and to an extent, the descending aorta) instead of being an obstacle becomes a safety barrier between the surgeon and the other pleural cavity. Instead of separating the growth bluntly and blindly from behind the arch it can be dissected under full vision.

The side chosen for the operation should be that giving the better exposure. Therefore to operate on the midesophagus through the left pleura is as unanatomical as it would be to operate on the lower end through the right pleura. By adoption of the method to be described, the question of lymphatic spread in no way affects this general proposition.

Stage 1: An upper left paramedian laparotomy is done. The abdomen is carefully explored. If there are no metastases, the greater curvature of the stomach is freed in its upper half. The vasa brevia, left gastroepiploic artery and the omentum are divided well away from the stomach to leave a vascular arch attached to the greater curve. The gastrophrenic omentum is then divided again well away from the lesser curve, and the left gastric artery is tied and divided near its origin. To reduce inflammatory reaction and adhesions, fine silk should be used throughout and the most careful hemostasis secured. Finally a loop of gut about a foot down the jejunum is chosen and a size 20 catheter inserted by Witzel's method. This is brought out, surrounded by omentum, through the lower end of the wound. If metastases are present, all that is done is a Janeway gastrostomy.

For 10 or 15 days after the first stage every effort is made to improve the patient's nutrition by a high carbohydrate high protein diet with extra vitamins. The jejunostomy makes this possible.

Stage 2: With the patient in the left lateral position and a sandbag under the chest the whole of the right sixth rib from the neck to its cartilage is removed and the chest entered through its bed. If after careful examination the growth seems removable the lung is packed forward and the vena azygos pleura is then incised and just above and below the growth, pieces of tape are passed around the gullet to be used as guide ropes. The involved segment, together with any glands, is then slowly dissected free. Care must be taken to avoid opening the left pleura—a serious complication. There is no need to paralyze the phrenic nerve. The lower end of the esophagus is gradually freed by retracting the diaphragm dividing the branches of the vagi and keeping it on a stretch with spongeholders. The part in the esophageal hiatus is then freed with the index finger. A specially devised sickle-shaped retractor is now introduced into the hiatus. This instrument not only retracts and stretches the hiatus with its tapering end, but holds the diaphragm and under drawn up through the hiatus, the peritoneum is opened and then severed all around the circumferance and eventually the body of the stomach, the fundus up into the pleural cavity. Adhesions of varying strength will have formed in the interval since the first operation; these are separated. When the stomach is sufficiently mobilized so that the fundus reaches well above the growth the esophagus with a wedge of cardia is severed and the gap sutured and invagi-

nated. If any enlarged glands have now become evident along the upper part of the lesser omentum, it is probably safe to extend the excision to include part of the lesser curvature and still leave the fundus viable as the vascularity of the stomach is remarkable. The next step of the operation is to prepare the gastric bed on which the esophagus will lie. The upper end of the stomach is fixed in the angle between the vertebral bodies and mediastinum. Five or six interrupted silk sutures are placed along each edge to fix the stomach posteriorly on the anterior spinal ligaments and anteriorly to the anterior cut edge of the mediastinal pleura. The esophagus is then laid upon the stomach and the posterior layer of interrupted sutures is put in before cutting of the growth. A transverse incision is made in the stomach should be on the short side as it can easily be lengthened but once it is too long it will make for a faulty joint. (b) any bleeding point should be tied before proceeding as the time spent will be amply repaid by a clean field and accurate suturing; and (c) a small sucker with a hooked point should be kept just inside the stomach incision. The through-and-through silk should be sutured with a fine needle and fine silk the close interrupted sutures each carefully including the esophageal mucosa. All knots are placed on the inside. The anterior seromuscular sutures are then placed. Finally if it can be done easily the stomach edges or omental fringes are folded over in front of the anastomosis and sutured. The enlarged hiatus does not need stitching up it is only about the circumference of a wrist 3 or 4 sutures are, however placed between the stomach and its rim to prevent the small gut from passing through. Sixty thousand units of penicillin are sprinkled around the anastomosis. A No. 14 catheter is placed alongside the anastomosis with a second hole cut lower down to be just inside the pleura. This is brought out through the ninth intercostal space laterally to drain under water.

The chest wall is sutured in layers. During the stitching up the anesthetist endeavors to get the lung well expanded. Any air left is drawn out forthwith by suction to the catheter. Blood transfusion is given to the patient throughout the operation.

If there is an appreciable amount of bronchial secretion a careful bronchoscopic cleansing is done before the patient leaves the table.

Postoperative care consisted of blood transfusions, nourishment via the jejunostomy tube, oxygen daily stomach washings, and frequent roentgenograms of chest and stomach with barium. The blood protein should be estimated on the third day. Concentrated serum is given intravenously for edema of the bases of the lungs. Culture is made from the intercostal catheter after 3 days. The patient is out of bed and on a full soft diet in about 3 weeks.

The author reports 7 cases of esophagectomy with 5 recoveries.

SURGERY OF THE THORAX

439

The practical criterion is that the degree of malignancy to the patient, is the length of time the disease takes to kill him to the pathologist it is an opinion based on the postmortem findings and the appearance of the cells. For the surgeon it may be deemed as the liability to recurrence after apparently adequate removal.

MISCELLANEOUS

Dickson J. A., Clagett O. T. and McDonald, J. R.: Intrathoracic Gastric Cyst. *J. Thorac Surg.* 1946, 15: 318.

A white girl, 10 years of age, had a long history of repeated "pneumonic" attacks. Physical examination revealed diminished resonance, tubular breath ing, and increased conduction of voice sounds on the left side of the thorax. A roentgenogram showed massive atelectasis involving at least the lower lobe of the left lung and possibly part of the upper lobe. On bronchoscopy a great deal of purulent secretion was aspirated from the left side, but no evidence of a foreign body was found. However there was a definite narrowing especially of the posterior branch of the left lower lobe bronchus. Studies in which radiopaque oil was used confirmed this. At operation a primary left posterolateral incision as made and the pleura opened. The entire surface of the left lung was densely adherent to the thoracic wall. A line of cleavage was established between the visceral and parietal pleuras and a good fissure was found between the upper and lower lobes. It was possible to carry out hilar resection with individual ligation of the hilar structures. A large cystic mass was found in the medial portion of the lower left side of the thorax. The esophagus lying anterior to the cystic mass was identified. The cystic mass was very adherent to the medial and under surface of the lung and was first thought to be a cyst of the lung. It proved to be a congenital mediastinal gastric cyst which had become infected and established bronchial communication. Chronic suppurative disease was present in the bronchus of the lower lobe. Dissection was carried out down through the diaphragm with some difficulty. The entire cyst was removed. Ten

porary closed intercostal drainage was instituted and bronchoscopy was performed postoperatively.

Several unusual features about this case of intrathoracic gastric cyst are worthy of consideration. The first of these was its partial extension below the diaphragm. Reports of other gastric cysts indicate that they have been attached to the diaphragm or embedded in it but the authors believe that none of the intrathoracic cysts has extended below the diaphragm. In the author's case this extension was of considerable surgical importance because removal of it necessitated repair of the diaphragm following removal of the cyst.

The associated bronchiectasis in the left lower lobe was a second unusual feature. The cyst had apparently established bronchial communication. It is impossible to determine in this case what part peptic ulceration played in the establishment of such a bronchial communication. Unfortunately studies were not carried out to determine whether the contents of the cyst contained enzymes or acid. Because of the types of mucosal linings present including the parietal cells in sufficient quantity and the thick mucoid character of the contents of the cyst it does not seem unreasonable to assume that such a cyst was producing acid and peptic enzymes.

A third feature was that the cyst contained the esophageal as well as gastric type of mucosa as has been the situation in a few of the reported cases. A large number of parietal cells were found in the gastric type of mucosa. The wall of the cyst was composed of three distinct layers.

There was no intimate attachment of the cyst wall to the esophagus nor did the cyst and the esophagus have a common musculature. The latter situation was important because it permitted primary removal of the cyst in one stage. This is not feasible in many cases because of the intimate attachment to the esophagus. The firm attachment of the lower lobe of the left lung to the lateral portion of the lower wall did increase the difficulty of resection. As far as can be determined this is the first case in which an intrathoracic gastric cyst was associated with bronchiectasis had a portion of its wall extending below the diaphragm and was treated successfully by removal of the cyst and lower lobe of the left lung in one stage.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Brandon, W. J. At: Inguinal Hernia: The Unpredictable Result. *Brit. J. Surg.* 1946 34 13

It is becoming increasingly evident that the inguinal muscular mechanism is now regarded as the key to the problem of oblique inguinal hernia. We must therefore, obtain an accurate conception of the anatomy and function of this mechanism before turning to the problem itself.

It is not the presence of a patent process of peritoneum that accounts for the frequency of hernia in man, but a weakness in the groin which has resulted from his upright posture. The most potent factor in the production of an oblique hernia, certainly of the acquired type, is a prolapse of the cord. This prolapse may be due to a defect primarily affecting the valvular mechanism or may be secondary to an ineffective cremasteric recoil.

Simple shutter action provides complete protection to the posterior wall against the outward thrust of intra-abdominal pressure. When it fails two types of direct hernia occur: a saucer-shaped bulge due to the stretching of the cotyle posterior wall or a funicular sac which appears to the lateral side of the insertion of the conjoint tendon and is associated with a localized congenital weakness or defect in the transversalis fascia.

Any breakdown or malfunction of the inguinal mechanism leads ultimately to a prolapse of the cord. If a preformed sac is present, it is bound to prolapse with the cord so that its well defined anatomical neck comes to be distal to the internal ring. The full force of the intra-abdominal pressure through the incompetent valve mechanism against the anatomical neck sooner or later dilates the new neck of the sac and results in a congenital hernia.

In an acquired hernia, once the posterior wall has been torn, the fundus of the sac comes to lie outside the infundibuliform fascia and no longer meeting with any resistance, is able to accompany the cord as an oblique sac with all the known characteristics of an acquired hernia. Frequently the sac fails to disrupt the infundibuliform fascia and, therefore, lies within it, but in all other respects it remains characteristic of the type.

The main point at issue in considering the repair of an oblique inguinal hernia is how much reliance can be placed on a repaired inguinal mechanism. The presence of a sac is an essential component of hernia in childhood; a second factor is the undeveloped state of the inguinal canal. If the surgeon attends to the first, nature looks after the second and success is assured. The author makes the following comment:

"When we consider the multiplicity of repairs, including simple herniotomy, we are struck by the fact that the only repair which provides a certain cure in adult life is complete closure of the inguinal canal

after removal of the cord and testis. It was on this fact that I based my solution, for every repair (with the exception of Schmieden's operation and my own modification of Ogilvie's method of mobilizing the cord in the lateral direction to allow complete closure of the inguinal canal) preserves the inguinal mechanism in some degree, and it is the preservation of this mechanism either wholly or in part that has made the repair of any given oblique inguinal hernia an unpredictable result." LEE PUTLAND M.D.

Dantlo, R.: Transplantation of Dermis in the Treatment of Eventrations (Transplantation de derme pour la cure des éventrations). *Presse méd.* 1945, 54 680.

Simple closure of eventrations by suturing the various layers of the abdominal wall over them is often followed by recurrence. A method which prevents such recurrence is the suture of dermis over the opening. The dermis becomes transformed into true tendon tissue as shown by experiments on dogs. The stimulation of the graft is not only hormonal but functional. The stimulus is furnished by the muscle tonus of the tissue into which the dermis is grafted.

Before transplantation, the epidermis must be removed from the dermis by curettage or with a Thiersch knife. The latter method is probably preferable as infection has never been seen in such cases. If there is enough excess skin above the eventration it is removed and used for the transplant. Skin from the thigh may be used. The grafted dermis must be stretched tightly like a drumhead and this tension must be kept up during healing.

The only contraindication is an enormous hernia lying outside of the abdomen, which would require so much force to replace it that failure of the circulation would be brought about. In large eventrations with plenty of skin above them a double-T incision may be made to produce two flaps, one of these is freed from its lateral connections with the abdominal wall but its connection with the subcutaneous tissue is left. This flap is then sutured to the aponeurosis and the other is turned over it like a double breasted coat. This double covering is not ordinarily necessary, however, as a single layer resists the pressure of the abdominal contents.

This method should become the classical one for the treatment of eventrations and large hernias. The operation is illustrated. AUBREY G. MORGAN M.D.

GASTROINTESTINAL TRACT

Remshaw, R. J. F., Kiskadden, R. M., and Templeton, F. E.: Gastrocolic Fistula; A Clinical and Experimental Study. *Gastroenterology* 1946 7 5

When gastrocolic fistula complicates the treatment of peptic ulcer a devastating syndrome results which is characterized chiefly by diarrhea.

steatorrhea weight loss, anemia and malnutrition. Previous reports in the literature indicate that these symptoms develop because food is shunted from the stomach through the fistula into the colon. The authors' experience with dogs and humans indicates that a shunt is not the major factor.

Gastrocolic or enterocolic anastomoses were produced in 7 dogs. Roentgenological studies revealed that all or a major part of the barium meal passed from the stomach into the upper small intestine in all dogs, although in 4 dogs a small or minor portion of the barium passed into the colon through the fistula. Similar studies in 10 human patients with gastrocolic, gastrojejunal, or enterocolic fistula revealed that the barium meal was passed from the stomach into the upper small intestine. In one dog the barium meal was observed to pass from the stomach into the small intestine, then into the colon finally the barium meal regurgitated through the fistula back into the stomach, from which it passed again into the upper small intestine. This same process was observed in one human patient. On postmortem examination of the dogs the small intestine especially the upper third revealed a striking subacute to chronic type of inflammatory infiltration limited almost exclusively to the mucosa of the papillae.

The development of anemia follows a definite pattern, although the authors admit that their studies are inadequate to describe this pattern in detail. The first change is to hypochromic microcytic anemia and if the animal survives long enough the anemia tends to become macrocytic hyperchromic.

It is suggested that the deranged digestive and absorptive functions of the small intestine may cause the clinical syndrome ascribed to gastrocolic fistula. Derangement of function of the small intestine is probably the result of damage to the intestinal mucosa caused by the passage of colonic contents through the small intestine. HAROLD LAUFMAN M.D.

Kristenson A.: The Pathogenesis of Ulcer (Zur Kenntnis der ulcuspathogenese) *Acta. med. scand.* 1946, Supp. 170 p. 31.

Since Virchow first assumed a vascular genesis for peptic ulcer many attempts have been made to prove that this condition is the result of a local disturbance in the circulation. The results hitherto have been contradictory.

The author points out that the chief source of blood to the first portion of the duodenum and the lesser curvature side of the pyloric antrum is the right gastric artery. This vessel is small and runs in the opposite direction to the hepatic artery the flow of which it originates. The small opening of the gastric branch is often further narrowed by changes in the media or the intima of the hepatic artery at the site of origin of the former. These arterial lesions may be the result of changes in the position of the pylorus and proximal duodenum as the patient goes from a prone to a standing position. The upright position would seem to diminish the circulation through the right gastric artery.

Fig. 1 (Kristenson) Roentgen picture of the stomach injected with contrast medium. Note the poor circulation to the pyloric region.

Injection preparations were made of the stomach and duodenum. These were x rayed and showed that the circulation to the pyloric antrum and first portion of the duodenum is decidedly less abundant than to the rest of the stomach and intestine. This poor circulation is further embarrassed in the upright position especially in individuals with marked gastroparesis.

The author concludes with his findings in regard to therapy. Small feedings are preferable to large ones since the former are less likely to disturb the stomach and duodenum hence less harmful to the circulation around the pylorus. Rest in a horizontal position is advised after each meal. Finally it is suggested that ulcer is the result of the upright position of the human race.

THEODORE B. MARSHALL, M.D.

Wilkinson, S. A. and Tracey M. L.: The History of Hemorrhage in Peptic Ulcer. *Gastroenterology* 1946 7: 450.

The mortality and significance of a first hemorrhage and of later hemorrhages vary widely in published reports.

This study concerns 140 proved cases of peptic ulcer admitted to the clinic which necessarily had a selective effect upon the series. Of the patients 125 were males the average age of the patients was 41.3 years and the average follow-up was 4.3 years. The over-all mortality was 3.5 per cent (5 deaths). Of the 140 cases only 2 were operated upon without previous medical management and 14 were operated upon after medical management prior to admission. One hundred and twenty four had medical management at the clinic and 41 of these, had eventual surgery.

There were 70 cases in which hemorrhage was the first symptom of the ulcer and there was only 1 death (1.4%) from the first hemorrhage. Twenty nine of these patients were more than 45 years of age at the time of their first hemorrhage.

The results of medical treatment were best in the 66 patients with only 1 hemorrhage prior to ad-

mission. Sixty-four of these were treated medically and 78 per cent responded satisfactorily. In this group there was a total recurrence of 35 per cent. Surgery was necessary in 21 cases (17%).

Seventy-four patients had more than 1 hemorrhage prior to admission. Seventy three were treated medically and 33 per cent responded satisfactorily. Operation was necessary in the cases of 45 patients (61%) and of these patients, one third had recurrent hemorrhages subsequent to radical operation.

Of the 140 cases, 41 were subjected to subtotal gastrectomy and recurrent hemorrhage appeared in 24%. Of 124 receiving medical treatment 30 per cent had subsequent hemorrhage.

In this series the first hemorrhage was not more serious than the later ones, and medical management offers a good chance of preventing further hemorrhage.

Patients with multiple hemorrhage do not respond well to any form of medical management and even radical surgery is not very satisfactory.

FREDERICK C. HOSKEL, M.D.

Tuovinen, P. I.: On the Relation Between Appendical Carcinoid and Appendicitis. *Ann. Chir. Gyn. Fenn.* 1946, 55: 60.

Carcinoid occurs in the stomach and gastrointestinal tract, preferably in the appendix. It is closely related to true carcinoma, 30 per cent of the cases showing invasion in the neighboring tissues and metastases in the mesenteric lymph nodes and in the liver. Clinically and histologically however the disease presents many features of appendicitis: tumor cells are mixed with inflammatory cells (polymorphonuclear plasma cells, and lymphocytes). The growth originates in the deeper epithelium cells of the crypts.

The author discusses 3 cases: 1 carcinoid which showed the clinical picture of acute appendicitis. He

believes that carcinoid may sometimes be an etiological factor of acute appendicitis.

WILHELM M. SOLMITS, M.D.

Scott, W. J. M., and Serenatti, O. J.: Megacolon; Mechanisms and Choice of Treatment. *Surgery* 1946, 30: 603.

Among the last 250,000 admissions to the Stroy Memorial Hospital, Rochester, New York, the authors found 31 cases of megacolon. Because so few cases are seen, there exists in the literature a conflict of ideas about both the etiology and the method of treating the condition. It is believed by the authors that megacolon is a syndrome rather than a disease entity and that at least 4 different causative mechanisms can be delineated. These are: (a) organic obstruction of congenital origin; (b) neurogenic dysfunction; (c) functional obstruction from extreme redundancy (dolichocolon); and (d) metabolic factors extrinsic to the colon (hypothyroidism, avitaminosis, malnutrition, etc.).

When a patient with megacolon appears for treatment, the following plan of combined diagnostic classification and clinical management is followed:

1. Examination is carried out to exclude organic obstruction of congenital origin. A tremendous dilatation of the colon may in the presence of normal innervation, musculature, and mucosa, be associated with congenital anomalies in the development or fusion of the proctodeum, which causes a high grade but incomplete obstruction of the lower large bowel. After several years of such obstruction, secondary changes due to dilatation, erosion, and fibrosis may supervene and affect bowel function. It is surprising how such a bowel will retain good emptying power.

2. Factors depressing the metabolic effectiveness of the smooth muscle of the colon are searched for and treated if found. The authors are unable to state whether such cases can be considered as definite clinical entities.

3. These two causes of disturbance in the emptying of the colon account for only a small minority of the cases. The remainder are then classified as idiopathic megacolon and the patients are put on a medical regime consisting of repeated colonic irrigation, mineral oil, occasional very mild cathartics, vitamin supplements, low roughage diet, and parasympathomimetic drugs. This regimen usually produces some improvement in symptoms which may be sufficient to warrant its continuation as the only form of therapy.

4. If conservative treatment fails to relieve symptoms after a thorough trial then one of 2 courses is taken: (a) the use of a spinal anesthetic motor test (anesthesia, at least to the costal margin, has to be achieved if the test is to be considered adequate) in cases in which the x-ray evidence is not strongly suggestive of dolichocolon; if, within a few minutes after induction of the anesthetic, the colon vigorously expels most of its contents, which the patient was unable to do voluntarily, the megacolon then is considered to be due to neurogenic dysfunction; (b) im-

Fig. 1. (Tuovinen) The tumor fills the appendical lumen. Strong proliferation of the connective tissue (38).

mediate exploration and resection of the colon in cases in which the x ray evidence of a functional obstruction from redundancy (dolichocolon) is convincing.

5. When satisfactory spinal anesthesia is ineffective then the case is classified as dolichocolon and resection is carried out as under (b) even though the evidence from the routine barium enema may not be sufficiently clear cut to make the differentiation between neurogenic and dolichocolon types. In the cases of the latter type it was found that the fundamental mechanism in production of the megacolon was a functional obstruction apparently due to an abnormal increase in the length of the sigmoid. When this abnormally long loop is filled it causes a kinking just proximal to its fixed point namely just above the rectosigmoid.

6. When spinal anesthesia is effective then the previous conservative régime is continued for at least 3 months more and may be repeated if gradual improvement in symptoms does not appear.

7. Lumbar sympathectomy is advised only for the small number of patients who respond dramatically to spinal anesthesia but who fail to obtain relief of symptoms after one or more such inductions.

8. The authors experience has recently led them to advise early operation in certain young children in whom a marked obstipation has been present since birth, and whose barium enema shows extreme redundancy of the colon with kinking just proximal to the rectosigmoid. In these cases it has been found that conservative measures and parasympathetic drugs are usually ineffective. In such instances when in addition to the previously mentioned findings, haustral markings are absent in the left colon resection of the redundant colon has been combined with left lumbar sympathectomy without a spinal anesthetic motor test being carried out. Whether this combination offers more than resection alone is not yet proved.

9. In any case when resection of the colon is carried out for dolichocolon, utmost care must be taken to prevent the subsequent development of any obstructive sequelae. It is believed that a long side-to-side anastomosis placed between the taeniae is the preferable type of reconstruction under the circumstances although ordinarily the authors choose an end-to-end anastomosis, usually of the aseptic type, for most resections of the colon.

Included in the discussion are illustrative cases and reproductions of roentgenograms.

EUGENE J. AUDI, M.D.

Herrmann, L. G.: The Management of Megacolon (Hirschsprung's Disease). *Surg Clin N Amer* 1946, 26: 1170.

Before discussing the treatment of megacolon the author briefly reviews certain theories concerning the genesis of megacolon, pathologicophysiological considerations, the diagnosis of the condition, and the pathological changes in megacolon. Under the last heading are included statistics which indicate that

about 33 per cent of the patients have involvement of the sigmoid colon alone. Figures compiled by the Mayo clinic reveal that 42.3 per cent of cases seen at the Clinic have had involvement of the rectum and 11.5 per cent have had involvement of the cecum. The parts of the colon proximal to the hepatic flexure were involved in 26.9 per cent of their cases. In all of the author's cases there was involvement of the sigmoid colon and of the portions of the large bowel immediately adjacent and proximal to the sigmoid colon.

Examination of these patients on admission often reveals that the distal part of the colon is packed with feces causing subacute colonic obstruction with marked gaseous distention of the entire colon. If at this time rectal examination reveals the presence of congenital strictures of the rectum they must be treated by regular dilatation with the finger or with soft rubber bougies, before any other form of treatment is instituted. Adolescent children and young adults have reported weeks of relief following a single manual dilatation. Overstretching of the sphincter muscles usually leads to a short period of fecal incontinence. The age of the patient and the extent of involvement of the colon usually serve as valuable guides for therapy since young children should always have the benefit of prolonged medical treatment and those children over 5 years of age with extensive involvement of the colon should have the benefit of properly planned and executed surgery. In the medical management of megacolon, acetyl-beta-methylcholine (mecholyl) has been used. Experience has shown that the optimum times for its administration are (1) 30 to 60 minutes after breakfast (2) in the midafternoon or (3) at any juncture to parallel and enhance an observed daily intestinal rhythm. Nausea, vomiting and abdominal pain result if the drug is given before breakfast. It should be administered for a 5 to 10 day period if it is expected to correct an autonomic imbalance with the establishment of new reflexes which are necessary to regulate intestinal function. An average initial dose of acetyl-beta-methylcholine bromide for patients with megacolon is 0.1 gm. increased if necessary, to 0.2 gm. within 2 to 3 days. Then after several more days with this daily dose, if bowel function is still not well established, an additional dose of 0.1 or 0.2 gm. in midafternoon may be prescribed. As the drug becomes effective in bringing about more normal function of the bowel daily enemas are discontinued but the oral administration of mineral oil is continued because of its lubricating action in the colon. 0.2 gm., given each morning and in midafternoon is sometimes required to initiate bowel movements. If this quantity of the drug produces diarrhea, the dose is then reduced to 0.1 gm. When the patient becomes stabilized on a dose of the drug which produces one or two stools daily he is usually discharged from the hospital with instructions to take 0.2 gm. of acetyl-beta-methylcholine bromide each morning about 30 minutes after breakfast and 1 or 2 tablespoonfuls of mineral oil each evening. He is seen again in 2 weeks.

An occasional enema is used if the patient becomes constipated or is troubled with gaseous distention of the colon.

The author is convinced that medical management of megacolon must be vigorously employed to minimize distention of the colon and to prevent nutritional changes in children at least up to the age of 5 years. Medical management should be continued after that age especially when the child continues to grow normally and continues to have satisfactory evacuations of the bowel. Proper preoperative medical management is frequently overlooked so that patients come to operation unprepared for an extensive surgical procedure.

The surgical measures used in the management of megacolon are (1) emergency procedures after some acute surgical catastrophe such as volvulus, complete intestinal obstruction, gangrene of the obstructed loop of bowel or peritonitis from perforation of the colon has occurred. (2) elective procedures such as sympathectomy or colectomy, either of which may be done alone or in combination.

Of 117 cases of megacolon subjected to sympathectomy (collected from the literature) complete relief was reported in 38 cases, and improvement in 64; there was failure to obtain benefit in 12 patients and 3 died. In the author's series of 19 patients with congenital megacolon with an age distribution from 2 months to 30 years, 14 patients were subjected to sympathectomy. Only 1 of these failed to obtain satisfactory function of the bowel following operation together with many months of intensive medical management.

Sympathectomy will not produce satisfactory results in cases in which the muscle power of the colon has been lost. It has been observed that patients who showed hypertrophy of the colon and visible peristalsis did well following sympathectomy. When hypertrophy of the colon was absent, the improvement which followed the sympathectomy was minimal. In those patients in whom the disturbances of the colon had progressed to the stage of marked dilatation with thin weak musculature of the colon, the results following sympathectomy were completely unsatisfactory. These patients were in constant danger of great gaseous distention of the bowel and kinking of the sigmoid loop.

Technically the author believes that the operation of abdominal sympathectomy should be performed by the transperitoneal route since that approach also affords an excellent opportunity for the surgeon to examine the entire colon. By this route, both lumbar sympathetic trunks and their ganglia can be removed at the same operation. In the more advanced cases of megacolon, the author and his associates have utilized the abdominal sympathectomy operation by way of the transperitoneal route and have removed most of the preaortic plexus of sympathetic nerves together with the inferior mesenteric plexus and its ganglia, the superior hypogastric plexus, and both lumbar sympathetic trunks with the second and third lumbar sympathetic ganglia.

The operation of sympathectomy does not always immediately restore the involved bowel to normal functional activity. It is sometimes necessary to use daily enemas, mineral oil, and even mild laxatives for several weeks before the habit of spontaneous evacuation of the bowel is established.

It is believed that partial colectomy is indicated in the segmental type of megacolon when only a small portion of the colon is hypertrophied and dilated, and the adjoining segments of the colon are relatively normal. The mortality in this type of operation is much lower than in those wherein extensive resection of the colon is necessary. The disturbing feature about the operation of segmental resection of the colon is not the immediate mortality but the fact that progressive dilatation of the segment of the colon proximal to the portion which had been resected frequently takes place. Usually however the resection of segments of the colon gives excellent end results and removes the danger of volvulus which develops all too frequently after sympathectomy. Patients with megacolon who have not been benefited by the combination of good medical management and sympathectomy should be subjected to partial or total colectomy if they can no longer be benefited by less drastic measures. In addition, those cases of megacolon which are due to low grade mechanical obstruction of many years standing, and not relieved by surgical removal of the obstructing lesion should be subjected to colectomy. Subtotal colectomy should be done also on those patients with megacolon who show no contraction of the bowel or evacuation of feces following spinal anesthesia, and for whom intensive drug therapy fails to reduce the size of the involved colon or to re-establish peristaltic activity.

The removal of a greatly dilated and thickened portion of colon is a somewhat different surgical procedure than the resection of a diseased portion of an otherwise normal colon. It is suggested that all of the involved colon should be resected by a one stage aseptic procedure, and, when possible, a temporary double-barrel colectomy should be constructed. This colectomy can be closed any time from a few weeks to several months, but not until the patient has shown definite general improvement. If the caliber of the entire colon is greatly increased it is wisest to remove it entirely or at least to the upper part of the rectum. The proximal end of the rectum and the distal end of the terminal portion of the ileum are brought to the outside of the abdomen, the final anastomosis should be made as a second stage procedure at some later date. The above described method of approach allows the saving of some portions of the colon which may be showing only secondary changes that might be reversible.

It has been found that a liberal left rectus incision is satisfactory for it affords adequate exposure of the splenic flexure of the colon which occasionally is very difficult to mobilize adequately. There is usually elongation of the mesentery of both the sigmoid and the descending colon making easier the mobilization

of an enlarged colon. The anal sphincter muscles should be forcefully dilated at the completion of the colectomy and when the colostomy is closed.

Because of the poor healing qualities of the enlarged bowel, the result of long-standing distention and lymphatic stasis in the tissues, the single stage resection of a part of the colon in megacolon and an immediate anastomosis between the proximal and distal segments of the bowel is fraught with danger of serious complications. This one stage procedure is not recommended in the management of the more advanced types of megacolon.

LIVER, GALL BLADDER, PANCREAS AND SPLEEN

Colp, R.: The Treatment of Postoperative Biliary Dyakinesia. *Gastroenterology* 1946 7: 414.

A review of some of the studies of cholecystectomy series shows symptomatic cure or improvement in approximately 80 per cent of the cases of cholelithiasis and a much lower and more variable figure for cases of noncalculous cholecystitis. The patients with recurrent symptoms respond in a fairly high percentage to medical management but in all of the series a few cases because of persistence or intensity of post-operative symptoms, again needed surgical exploration. In this latter group the surgical findings varied and included such findings as calculi in the stump of the cystic duct, calculi in the common duct, acute pancreatitis, cholangitis, stricture of the papilla and pancreatic cyst. However, in the majority explored no gross pathological findings were found. The absence of organic findings upon which to base an explanation for colic in these cases leads to consideration of a functional factor or dyskinesia of the sphincter mechanism to explain not only recurrent or persistent symptoms following cholecystectomy but the pathological physiology of gall bladder disease.

The author recommends that the treatment of biliary dyskinesia at first be directed along a conservative medical course. Reflex or emotional factors should be sought. In the latter reassurance and mild sedation may be effective. In menopause or difficulties in menstruation proper hormone therapy may be effective in relieving the symptomatology. Constipation may be the reflex cause of the symptoms which may consequently be relieved by bile salts, mineral oil, magnesium sulfate, or daily sodium carboxylate enemata. In patients with recurrent attacks of colic, elimination of biliary stagnation is attempted by frequent small feedings for each period of gastric digestion is followed by a discharge of bile into the duodenum. Gastric acidity, if high, is controlled by antacids and a bland nonirritating diet to prevent flow of free acid into the duodenum which causes sphincter spasm. Sodium nitrate or trinitroglycerol controls the colic in some cases but more often morphine sulfate may be necessary to relieve the pain. Persistent or increasingly severe symptoms make

surgical exploration mandatory to rule out an organic cause, or as in the 8 cases presented by the author to eliminate surgically intractable dyskinesia of the sphincter mechanism.

Surgical exploration should be meticulous and special attention should be given to the retroduodenal and papillary portions of the choledochus, a common hiding place for residual calculi. If organic exploration is totally absent it is then reasonable to consider intractable dyskinesia of the sphincter mechanism and this may be primary or secondary to a hypertrophy, stenosis or inflammation of the papilla. Stenosis of the sphincter is best circumvented by choledochoduodenostomy. A spastic sphincter may be dilated by sounds or other means but these do not guarantee lasting relief. Sphincterotomy offers a more direct and definitive approach to the problem of spastic sphincter but has not been widely practiced either because surgeons did not believe dyskinesia of the sphincter was responsible for the symptoms or because they did not wish to use such a formidable procedure for a functional disease. The author submits the results in 8 cases in which he divided the sphincter without opening the duodenum, by means of an instrument first described by him in 1938 and which he calls a sphincterotome. This instrument sections the sphincter endocholedochally. Following the procedure the common duct is drained by a T tube and by this means manometric readings of the intraductal pressure, lipoidal studies, and x ray studies may be made.

Seven of the 8 patients in whom the sphincter was divided had had recurrent symptoms of pain, chills, fever or jaundice. Of these 6 experienced relief over a period of observation from 2 to 8 years following sphincterotomy. One of them had the retained stump of the gall bladder fixed to the side of the common duct which was dilated and thickened so relief may have been caused by its removal. One patient with recurrence of jaundice may possibly have passed a stone just prior to the operation which may have accounted for relief of the symptoms. In the remaining 4 no organic pathology was found. In 1 case the sphincter was divided at the time of the cholecystectomy, because there were only a few stones in a gall bladder showing little change but the patient had had an attack of jaundice with colic. The common duct was normal and did not contain stones. The patient was free from discomfort 5 years after operation.

FREDERICK C. HORNEL, M.D.

Kaljeer, R.: Clinical and Pathohistological Aspect of Acute Cholecystitis. A Comparative Investigation. *Uppsala läk fören förh* 1946 51: 313.

The clinical classification of acute gall bladder disease as acute cholecystitis or as noncomplicated stone colic has been based chiefly on the presence or absence of hypernormal temperature and as a rule no pathohistological evidence has been brought forth to support this division. A nonselected series of 176 surgically resected gall bladders were studied histologically sections from various parts of

the gall bladder having been taken for purposes of examination and the findings were correlated with the temperature at operation or during the last attack.

From 21 patients who at the time of operation, ran a minimum temperature of 38°C there were only 3 specimens that showed no material signs of acute inflammation histologically. From a group of 82 patients who, during the last attack, had had a rise of temperature to a minimum of 38°C but at the time of operation had a maximum of 37.9°C there were 46 specimens (55 per cent) showing plain signs of acute inflammation and 12 showing slight signs of acute inflammation. It is difficult to gauge the remainder of these cases because of the possibility that an acute inflammatory process had subsided between the time of the attack and that of surgical removal of the gall bladder. However there were only 4 patients operated upon within a reasonably short time after an acute attack with a temperature of over 38°C whose specimens showed no acute inflammatory changes. From a group of 70 patients who during the last attack, did not have temperatures exceeding 37.9°C there were 48 specimens showing no evidence of acute inflammatory change whatever. In the remainder of this group there were only 6 specimens in which an acute cellular infiltration of trivial appearance had occurred, not causing a rise of temperature beyond 37.5°C .

The conclusion to be drawn from this study is that the classification of a clinical series of cases of gall bladder disease into the groups "acute cholecystitis" and "noncomplicated stone colic," with division at the temperature level of 38°C , is fairly well substantiated by the pathoanatomical picture. Although there are patients running temperatures below 38°C with pronounced acute changes in the gall bladder as well as those with temperatures above that level having no acute changes these divergences are not particularly frequent.

JOHN L. LAMOREUX, M.D.

Lasala, A., and Uribe, J. V. Jr.: The Common Bile Duct. Surgery of the Pancreatic Portion. Technique of Finocchietto. (Colédoco. Cirugía de la porción pancreática. Técnica de Ricardo Finocchietto) *Presi med argen* 945 331:449

Gall stones fixed in the pancreatic and preangular portions of the common bile duct are always of surgical importance. If they are firmly attached, they cannot be mobilized upward with finger maneuvers, nor grasped with clamps as there is always the danger of duct lesions.

To remove such stones, the transpancreatic or transduodenal approach is employed. Moynihan advises sectioning of the pancreas with the thermocautery or separating it by blunt dissection. Walzel Kehr and others advocate transduodenal choledochotomy. The transpancreatic approach has often been criticized for there is always the danger of sectioning this gland which sometimes lies like a

Fig. (Lasala and Uribe) Locations of the common bile duct.

broad coat upon the choledochus. R. Finocchietto proposed the interpancreatic approach after many anatomic studies on the pancreatic choledochus. This method was used for 6 years with excellent success.

Modern anatomic studies of Chylivich and Kozhventer, Belou, Zuckerkindl, and others, show that the choledochus is not intraglandular as was thought some time ago, for it is only partially engulfed by the gland. Actually it lies in a channel more or less deep at the posterior side of the gland and separated from it by loose connective tissue. This level must be found and the connective tissue removed in order to separate the pancreas and reach the choledochus without injury of the gland.

The following results have been observed by Finocchietto in 100 dissections.

In 7 cases the choledochus was situated in a small depression covered exclusively by the lamina of Treitz and the pancreaticoduodenal vessels (Fig. 1 A). In 4 cases the choledochus was in a slightly deep depression but covered in a small extension by

Fig. 7

Fig. 7. Drainage.

a portion of pancreas. In 3 cases it was situated in a deep depression totally covered by two thick flaps of the pancreas (Fig 1 B). In 7 cases the gland covered the choledochus and apparently there was no interstice. The small branches of the pancreaticoduodenal vessels were ligated and the pancreas could be opened in the form of the leaves of a book and another deep layer was seen (Fig 1-C). In 74 dissections after separation of the superior pancreaticoduodenal vessels it was possible to uncover a good portion of the duodenum by opening the pancreatic leaves (Fig 1 D).

In 5 cases the posterior side of the choledochus was overbridged by pancreatic tissue in a thin coat of 1 or 2 mm.

Finocchietto says that therefore in this series of dissections, and according to the anatomists, the choledochus runs in a depression of the posterior side of the pancreas in 11 per cent of the cases, and in a channel in 89 per cent. According to the surgeons, in 84 per cent of these 89 per cent of cases a single furrow of this channel could be made by just ligating and sectioning some little pancreaticoduodenal vessel and the choledochus found without sectioning even the smallest portion of the gland. In only 5 per cent of the cases would it have been necessary to cut the parenchyma to a small depth.

The study of the vessels of this territory described in the classical work of Rio Branco and in the modern one of Pierson is very interesting. The choledochus runs first side by side with the superior or posterosuperior pancreaticoduodenal artery being crossed by these later to join them at the postero-inferior pancreaticoduodenal artery in a bow from which start many small pancreaticoduodenal vessels. The ligation and cutting of these vessels render the pancreatic leaves movable.

In Finocchietto's surgical technique the operating table must be horizontal with no dorsal angulation and a Potter Bucky screen is applied to obtain systematically an operative cholangiography by Mirizzi's method. Once the stone is localized in the pancreatic or presuprarenal choledochus, the following operation is performed.

Step 1. Loosening of the duodenum and pancreas through Kocher's maneuver. Gentle pushing upward of the stone can be tried, or it can be grasped by a clamp through a supraduodenal choledochotomy. If it is not possible to remove it an intra-pancreatic choledochotomy is done.

Step 2. Insertion of a Bénédict probe, size 30, into the supraduodenal choledochotomy to locate the choledochus and determine the thickness of the gland upon it. An interstice has to be looked for. It is commonly covered by areolar tissue and can be separated by disrupting the Treitz lamina.

Step 3. If step 2 is impossible ligation and section of the small pancreaticoduodenal vessels forming a bridge between the pancreas and duodenum must be done (Fig 2). The ends of the ligatures must be left long in order that they may be grasped with forceps. The bridge formed by the fascia of Treitz

will be cut (Fig 3). Once the areolar interstice is found, the choledochus is reached by retraction (Fig. 4). In other cases the pancreatic flap lies crosswise and its retraction is easier (Fig. 5).

Step 4. The surgeon takes the loosened pancreas in his left hand and, with his forefinger pressing on the anterior side of the pancreas, pushes the stone toward the posterior side of the pancreas (Fig. 6). Transversal choledochotomy is performed to avoid section of the sphincteric fibers. The stone is removed.

Step 5. Suture of the inferior choledochotomy by joining of the edges of the pancreatic parenchyma and knotting of the suture ends (left long with a forceps attached).

Step 6. Fastening of the loosened duodenum and pancreas. Rubber dam drainage is left behind the pancreas at the level of the inferior choledochotomy. At the superior choledochotomy a thin Kehr's tube is put in to control postoperative biliary hypertension, because rupture of the sutures of the inferior choledochotomy or an infection could occur. This is also of benefit in postoperative cholangiography. Next to this tube, gauze and rubber dam drainage is placed (Fig 7).

H. MANN, M.D.

Biegard J D: Pancreatitis as a Cause of Complete Obstruction of the Common Duct. *Ann. Surg.* 94:6 4, 1931.

The author presents in detail the reports of 2 cases of relatively painless extrahepatic obstructive jaundice. In both cases there was chronic cholecystitis without stones and much evidence to support a diagnosis of chronic pancreatitis. Both patients recovered following surface drainage of the common duct.

In both cases the postoperative choledochograms showed narrowing of the distal end of the common duct suggestive of compression from pancreatic disease. In one case subsequent choledochograms were made and these showed a progressive increase in the filling of the constricted portion of the duct which was interpreted as evidence of release of compression.

From the evidence, it is suggested that the obstruction of the common duct in these 2 cases probably was caused by chronic pancreatitis. The evidence is offered in support of the hypothesis that on occasion the swelling of the chronic pancreatitis obstructs the intrapancreatic portion of the common duct.

In making the diagnosis of chronic pancreatitis with obstructive jaundice, it is assumed that (1) the jaundice is extrahepatic in origin (2) chronic pancreatitis exists and (3) the assumed inflammation of the pancreas is capable of obstructing the common duct.

A diagnosis of chronic pancreatitis can be made with certainty only by histological confirmation. An elevated serum amylase is suggestive. If not indicative, of inflammation of the pancreas.

Moore, M T : Symptomatic Abdominal Epilepsy
Am J Surg 1946 72 883

Epilepsy according to Hughlings Jackson, is the name for occasional, sudden excessive, rapid and local discharge of gray matter. Its manifestation in the patient depends upon the locus of the brain which discharges.

The more commonly observed motor Jacksonian seizure of isolated muscle groups is often the result of a discrete lesion (tumor, scar or other structural change) in the motor area but should the lesion which initiates paroxysmal cerebral dysrhythmias be situated in another portion of the brain than the motor area the symptoms would logically be reflected in the somatic or visceral component of the body dominated by that part of the central nervous system. Thus the author reasons it is conceivable that focal lesions of any one or all of the areas three, five, and six, of Brodmann of the cerebral cortex or diencephalon could produce under appropriate conditions, abnormal discharges which would lead to disturbed gastrointestinal activity and resultant abdominal pain. This condition he defines as symptomatic abdominal epilepsy.

Abdominal distress and even pain which according to one investigator is due to abnormal gastrointestinal movements has been observed to be a part of the preconvulsive aura of epilepsy. Wechsler and others have noted the occurrence of abdominal pain variously simulating gall bladder disease, peptic ulcer, appendicitis and renal colic in cases of cerebral lesions.

The author discusses 5 representative cases in support of his contention. Of these, one is a case of brain tumor of area six following the removal of which symptoms of recurrent severe epigastric pain disappeared. The second case is one of tuberous sclerosis with disseminated brain lesions in which one prominent symptom was recurrent attacks of severe abdominal pain. The third case is one of old cerebral trauma with numerous intervals of abdominal pain, nausea and occasional vomiting and diarrhea following the injury. Electroencephalographic studies approximated the pattern seen in idiopathic epilepsy and the patient was free of abdominal complaints following the institution of anticonvulsant medication. The fourth case is one of angioneurotic edema with focal cortical damage. The chief complaint was that of periodic cramping pain of the entire abdomen. On an anticonvulsant regimen this patient was free of pain for a period of 7½ months. On cessation of medication the attacks recurred and were again halted by dilantin sodium. A characteristic abdominal seizure occurred when the sedatives were replaced by sodium chloride without the patient's knowledge and complete relief was again afforded when anticonvulsant medication was resumed. In the last case no cerebral damage was demonstrable however the author believes that the prompt cessation of gnawing abdominal pain and accompanying epileptoid symptoms with anticonvulsants justifies the diagnosis of abdominal epilepsy.

The pathogenesis of abdominal epilepsy is discussed and a routine for the complete study diagnosis and treatment of the condition is listed.

WAYNE CAMERON M D

GYNECOLOGY

UTERUS

Mollinengo, L.: Association of Endocervical Carcinoma with Fibromyoma of the Body of the Uterus (Sull'associazione di carcinoma endocervicale con fibromioma del corpo uterino) *Ginecologia Tor* 946, 12 133

The simultaneous occurrence of fibromyoma of the body of the uterus and endocervical carcinoma has been observed by the author in 3 cases. Because of the difficulty in diagnosis which this combination presents, the importance of an endocervical exploration must be stressed. The precise diagnosis is important, as the presence of carcinoma suggests x-ray therapy while fibromyoma requires operative intervention.

This disease was suspected following a menorrhagia or metrorrhagia, and a discharge which varied from yellow rose red coffee-like, and fetid. The endocervical mucosa was curetted and a microscopic examination revealed the diagnosis. With involvement of the pelvic peritoneum, severe local pain was present, although similar pain may be caused by rapid growth or hemorrhage into a fibromyoma.

The treatment advocated by the author is a total hysterectomy either abdominal or vaginal, for carcinoma of the uterus, and a supracervical hysterectomy for fibromyoma. ARTHUR F. CIRIOLO, M.D.

Campbell, Z. B.: A Report of 2 798 Vaginal Hysterectomies. *Am. J. Obs.* 916 5 598

This report covers 2 798 vaginal hysterectomies for benign disease of the uterus performed at the Presbyterian Hospital, Chicago by the attending and resident staff. The mortality is compared with that of 4,483 vaginal and 40 587 abdominal hysterectomies reported in the literature. The mortality rate of the collected cases of abdominal hysterectomy is 7.5 times greater than that of the vaginal hysterectomy.

The author prefers vaginal hysterectomy because (a) it permits a more regular correction of all defects than do other procedures (b) the vaginal route causes less discomfort to the patient (c) no abdominal scar is produced (d) pulmonary complications and emboli are less frequent (e) thrombophlebitis and pelvic abscess are less common (f) trauma to the bowel postoperative adhesions, and ileus and bowel obstruction are infrequent (g) gas pains are less severe (h) it is less radical and safer than irradiation (i) it affords a safe approach to many forms of adnexal pathology (j) peritonealization can be accomplished as accurately as by the abdominal route and (k) stump carcinoma and persistent cervical discharge are prevented.

The author agrees with many who have advocated vaginal hysterectomy rather than abdominal hysterectomy in poor operative risks. It then seems logical

that vaginal hysterectomy is an even safer procedure in patients who are in better operative condition. Previous abdominal surgery need not always contraindicate vaginal removal of the uterus. The technical skill of the operator is of no greater importance than is the choice of method of approach or preoperative preparation of the patient, such as: (a) eradication of foci of infection (b) correction of anemia, and vitamin protein and fluid balance and (c) restoration of the normal vaginal flora. Metabolic hemostasis is vitally important.

Adequate training in vaginal hysterectomy will equip a surgeon with the confidence and ability to treat many other gynecological conditions by vaginal surgery to the great benefit of the patient.

JOHN R. WOLFF, M.D.

Falk, H. C., and Bunkin, I. A.: A Study of 300 Vaginal Hysterectomies. *Am. J. Obs.* 1946, 5 623

The authors report 300 consecutive vaginal hysterectomies with and without anterior and posterior vaginal wall repairs, performed on the gynecologic service at Beth Israel Hospital, New York, over a 5 year period from January 1940 through 1944. A group of 14 operators took part in the work all following a standardized fixation ligature technique.

According to the obstetric standard of morbidity (a rise in temperature to 100.4 degrees on any 2 days after the day of operation) 106 cases, or 35.3 per cent, were morbid. One hundred and ninety-three patients were given sulfonamides prophylactically following operation and 46 or 23 per cent, became morbid. 307 did not receive sulfonamides, and 56, or 18 per cent, were morbid. One hundred and sixteen patients had gross or microscopic cervicitis as reported by the pathologist and 25 or 31 per cent were morbid. Of the 384 patients without cervicitis 77 or 20 per cent showed morbidity. When vaginal hysterectomy alone was performed, the morbidity was 19.4 per cent. When perineal care was added, the morbidity was only 15.5 per cent, but when bladder repair was also done, the morbidity rose to 24.5 per cent. Bladder repair also increased the incidence of voiding difficulties. Of the 500 patients, 73 or 14.6 per cent developed pus in the urine. 34 of these had received sulfonamides prophylactically.

There was 1 death in the series, a mortality rate of 0.3 per cent. This followed a septic course with pelvic peritonitis, abscess and perinephritic abscess.

There were 3 cases of pyelonephritis, 1 case of pelvic phlebitis, 1 of pulmonary infarct, 1 of transient pulmonary edema, 1 of transient auricular flutter, and 3 cases of pneumonia. The bladder was injured twice but immediate suture led to recovery. There were no ureteral injuries, injuries to the rectum or fistulas. Postoperative bleeding occurred

twice once from the vaginal cuff, and once from the perineum. Two patients returned with ovarian cysts necessitating removal.

The authors believe that vaginal hysterectomy is an operation associated with a minimum of shock and hemorrhage, low morbidity and low mortality. It is the procedure of choice in the obese and the aged. Nulliparity is not a contraindication. The fixation ligature technique is safe and readily taught and learned.

JOHN R. WOLFE, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Mocquot, P. and Musset, R.: Nongravidic Ovarian Hemorrhages (*Les hémorragies ovariennes non gravidiques*). *Gyn. obst. Par.* 1946 45 337

Hemorrhages of the ovary may be secondary to a systemic or local pathological process. Infectious diseases like typhoid, smallpox, cholera, as well as poisonings with phosphorus or antimony, extensive burns, blood dyscrasias or cardiac failure are among the general processes which may cause ovarian hemorrhage while tumors, torsion of the adnexa and endometriosis are among the local ones.

More frequent but more puzzling as to their etiology and pathogenesis are the primary hemorrhages. These may either occur freely in the peritoneal cavity or form localized hematomas within the ovary. In hemorrhages bleeding into the peritoneum, the gross appearance of the ovary may vary considerably; sometimes it is enormous and of wine red color resembling splenic pulp on the cut surface, other times the volume is increased only in parts revealing hemorrhagic zones and cysts filled with blood. The amount of bleeding may vary from minor seepage to profuse apoplexy of the ovary which calls for immediate surgery. Often adhesions are found, but whether these are the cause or a sequel of the bleeding has not been decided. The histological examination shows that the hemorrhages may originate from a Graafian follicle or from a corpus luteum on the other hand, interstitial hemorrhages originating from the stroma seem to be not infrequent.

Very little is known of the pathogenesis and etiology of primary hemorrhages. Clinical and experimental experiences seem to indicate a hormonal origin. The most plausible theory is that a sudden excessive activity of the anterior pituitary lobe leading to hyperproliferation causes the syndrome but nothing definite is known yet of the mechanism. The hormonal theory is supported by the clinical picture: the hemorrhages have never been observed before the menarche or after the menopause, more than half of the cases occur in virgins only a short time after the menarche, other cases occur during lactation or in women with irregular menstruation. All this indicates a disturbance in the hormonal equilibrium. In the acute cases, the symptoms are dramatic, resembling those of ectopic pregnancy or acute appendicitis. On the other hand there are women who suffer from these crises more or less reg-

ularly between the twelfth and eighteenth days of the menstrual cycle, i.e. synchronously with ovulation. These crises are often violent, and are accompanied by vomiting and even syncope. Vaginal examination during the attack often reveals doughy swelling of one ovary with extreme tenderness. This sign clears up after a few days only to be repeated after 1 or 2 months.

The treatment should be surgical in the acute cases and conservative and symptomatic in the chronic ones.

MISCELLANEOUS

Scott, W. W., and Ekas, W. L.: An Operative Procedure for the Repair of the Urethrodiverticulovaginal Fistula. *Surgery* 1946 20 645

Urethrodiverticulovaginal fistula is an uncommon lesion. A review of much of the literature on diverticulum of the female urethra and the urethrodiverticulovaginal fistula revealed but two cases.

From the location and character of the urethrodiverticulovaginal fistula, it is reasonable to assume that it can be classified as an acquired rather than a congenital lesion. Furthermore, it would seem that the identical conditions which play a role in the development of the urethral diverticulum are the essential factors in its causation.

The authors state that while our knowledge of the symptoms of this disease is quite limited because of our meager personal observations and the scarcity of information on the subject in the literature, it seems safe to assume that for the most part these symptoms will be quite similar to those of the urethral diverticulum. In addition, in most of these cases there will be urinary incontinence concomitant with vaginal irritation and dyspareunia. In a case in which the tumor was present for some time before drainage was established, the patients were quite sick, having chills, fever, nausea and vomiting and low back pain. All of the patients had frequency, urgency, dysuria and urinary obstruction in varying degree.

The diagnosis of this condition is not difficult once the possibility of a ureterovaginal or vesicovaginal fistula has been ruled out and the presence of an urethral diverticulum proved.

The successful repair of this condition, as in the case of the vesicovaginal fistula, depends in no small measure upon the preoperative preparation and most especially upon meticulous care following operation.

The authors have presented an operative procedure used successfully in the repair of 2 of these cases.

HARRY W. FORD, M.D.

Beecham, C. T.: Conservative Surgery in Endometriosis. *Am. J. Obst.* 1946 53 707

Conservative surgery in the treatment of endometriosis is the predilection of all gynecologists. To the author, conservative gynecological surgery means the removal of the least possible tissue to obtain the

desired result. Hence every attempt is made to preserve ovarian function to the age of 45 years or beyond if the lesion permits, and in previously sterile women, to preserve the childbearing capacity to the age of 40 years. A patient with endometriosis who has her family obviously minimizes the latter consideration.

The author surveys 80 conservative cases encountered in the past 6 years. By means of conservative methods, such as removal of endometrial implants, resection of diseased ovaries, and the correction of a retrodisplaced uterus, he has been able to salvage the childbearing capacity in 32 cases, or 52.5 per cent. Ovarian tissue was salvaged in whole or in part in 14 patients (17.5%) but this was impossible in 15 instances (18.75%). Nineteen of the patients were more than 45 years of age and radical surgery was employed in all but 3. In the 6 years, only 2 of the conservatively treated patients had recurrent complaints.

Since 42 per cent of the patients had a retrodisplaced uterus, the author believes that there is a close relationship between this condition and endometriosis. Breeham recommends that women with nonpathological retrodisplaced uteri be observed at regular intervals for signs of fixation indicating a surgical need for treatment of probable endometriosis.

The author concludes that conservative surgery is definitely worth while and should be the major consideration when operating upon endometriosis.

JOHN R. WOLFE, M.D.

Tellum, G.: Arrhenoblastoma—Androblastoma. *Acta path. microbiol. scand.* 946 23 32.

The author here describes a series of homologous tumors of the ovary and testis which he calls the arrhenoblastoma-androblastoma series.

He states that in studies of ovarian tumors made during the past 25 years, histogenesis was the basis for classification. Classification however is still uncertain in some tumor forms because of the highly variable histological pattern.

He refers first to the ovarian arrhenoblastoma which is characterized clinically by a more or less pronounced masculinizing effect and, according to Robert Meyer originates from testicular elements remaining from the early stages of gonadogenesis. There is the one extreme represented by the testicular adenoma of the ovary and the other extreme which is a diffuse blastema often with sarcomatous differentiation and a more or less pronounced tendency toward epithelioid differentiation. He makes the observation, as others already have, that the strongest virilizing effect is noted in patients with the least differentiated forms of tumor. The clear cut tubular adenoma shows hardly any hormonal effects.

He reviews Robert Meyer's concept of the origin of the ovarian arrhenoblastoma—the view which is now widely accepted, namely the arrhenoblastoma originates from the undifferentiated germ cells that

have kept their germinal potency throughout the period of development. Thus, if part of the rete blastema with its medullary cords remains undifferentiated and later for some unknown reason, commences to grow a tumor of masculine germinal epithelium may develop in the rete ovary.

The author points to the morphological congruity between certain testicular tumors and ovarian arrhenoblastomas apart from the clear cut tubular adenoma. He refers to these homologous tumors as the androblastoma series.

He describes a feminizing testicular tumor which has the same structure as an ovarian arrhenoblastoma. The patient from whom it was removed presented himself with increasing gynecomastia, a loss of libido and a testicular tumor. The tumor showed all the stages of differentiation seen in the typical virilizing arrhenoblastoma of the ovary. The author shows the microscopic pictures of this tumor and points to its close similarity to an ovarian arrhenoblastoma. He likewise shows photomicrographs of 7 other testicular tumors and similar microscopic pictures from ovarian tumors. The morphological likenesses noted in this feminizing tumor and in the virilizing arrhenoblastoma along with the gradual transition in some parts to a structure like that of a clear cut lipid cell tumor allows the author to elucidate on several points.

He says that it proves Meyer's view that the ovarian arrhenoblastoma also originates from a particular testicular anlage. One can follow the continuity of various stages of differentiation in this male tumor as in the ovarian tumor described by Meyer. This gradual transition from tumor tissue of the arrhenoblastoma type to a clear cut lipid-cell tumor is taken to prove that the latter represents a particular form or variant of the androblastoma series. In the ovary we meet with virilizing or defeminizing tumors rich in lipid; the histogenesis of which has been disputed. It is said that they arise from aberrant adrenal cortex (ovarian hypernephroma) or they have been taken to be luteal cell tumors (luteoma) lutealized granulosa cell tumors, or the neutral masculinoblastoma. The author believes that these tumors in the ovary are particular form of the arrhenoblastoma series originating through one-sided differentiation of lipid cells within the blastema.

The tumor described in this paper with its gradual transition from tumor tissue of the androblastoma type to lipidoid cell tumor—which histologically corresponds to the tumors described in the ovary as luteoma and adrenal tumor—affords a definite proof of such a histogenesis. In other words, most of the cases described as luteoma adrenal, or hypernephroid tumors have to be looked upon as representing a particularly lipidoid form of the ovarian arrhenoblastoma.

It is a peculiar fact, he states that tumors of this series which are virilizing in women may have feminizing effects in men. This corresponds to the effect described for certain tumors of the adrenal cortex. In men occasionally feminization with gynecomast-

the testicular atrophy and increased estrin values in the urine are noted. The paradoxical hormonal effect in men is thus common to all these tumors, including the androblastoma which he describes.

The author presents one chart showing the homologous tumors of this series together with similar but not homologous tumors of the granulosa group.

HENRY C. FALK, M.D.

Vaccaro H. Cabezas J. and Berrios, H.: The Importance of Lysozym In Gynecology and Obstetrics (Factores inespecificos de defensa en ginecología y obstetricia. Importancia del lisozima) *Bol Soc chilena obst gín* 1945 10 233

The importance of lysozym as a defense factor in gynecological and obstetrical patients was evident in the following observations. In gynecologically normal women the vaginal flow contained a high lysozym titer while the cervical flow although containing lysozym contained a lower titer or in some cases none at all. No constant parallel was found between the lysozym content of the cervix and that of the vaginal wall. Lytic inhibitory power was found in dilutions of 1:800 in 6 hours of contact while in the same length of time the highest dilution in which the cervical content showed action was 1:400. The vaginal flow without previous dilution had its lytic inhibitory action after 5 minutes while the cervical flow under the same conditions showed its power after an hour.

In gynecologically affected women under identical conditions as those shown above, there was an appreciable diminution of the lytic inhibitory power

while the maximum effective dilutions were half of those in the normal group. The lysozym contents of the cervix and vagina were similar to those of the normal group and were predominant at the vaginal wall level.

Pregnant women revealed an increased lysozym content in the genital flow however, the stage of pregnancy has no influence on the lysozym titer. The difference between cervical and vaginal concentration was similar to that in the previous groups.

In puerperal women the lochia had a lower lysozym content than that of pregnant women of the normal group and of those with gynecological diseases. The lysozym content was nil in most of the cases.

Amniotic fluid contained practically no lysozym.

The following procedure was used in determining the lysozym titer: 10 c.c. of sterile serum were washed against the cervix or vagina and this specimen was diluted with 10 c.c. of sterile physiological serum. This mixture was placed in a water bath at 60 degrees for $\frac{1}{4}$ hour 3 times, with an interval of 24 hours each. The resulting solution was sterile having a total lysozym content. One cubic centimeter of the above solution is added to 0.1 c.c. of a bacterium emulsion of *Bacterium Sarcina* and incubated at 37 degrees for 24 hours. One cubic centimeter is removed placed in a test tube containing agar at 42 degrees, and this mixture is then placed in a petri dish and incubated at 37 degrees for 24 hours. It is then examined at 24, 48 and 72 hours and compared with the serum from 3 controls.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Mayer C.: The Quantitative Analysis of Urinary Estrogens in the Course of Pregnancy (*Le dosage de l'œstrogène urinaire au cours de la grossesse*) *Brazzaville méd.* 946 26 8

Estradiol is the fundamental estrogenic substance elaborated by the ovary. Two derivatives of this substance occur in human urine, estrone and estril. It is the former however which is chiefly responsible for the estrogenic activity of female urine.

Two methods are utilized for the quantitative analysis of urinary estrone. The biologic method is based on establishment of the minimal dose of extract capable of provoking keratinization of the vaginal cells in the spayed mouse and rat. The colorimetric method is based on the fact that pure estrone reacts with betanaphthol sulfuric acid to form a rose color. This reaction is quantitative and the intensity of color change may be measured by comparison with standard solutions. Other substances present in the urinary extract will also produce a color but the color due to estrone is destroyed by the addition of hydrogen peroxide. Hence accurate estimation involves a determination of the difference in color before and after the addition of peroxide.

A review of the variations reported by other investigators is confusing because of different unit measures. To eliminate this confusion the author has proposed the following arbitrary classification:

- 1 mouse unit equals 8 international units
- 1 rat unit equals 32 international units.
- 1 international unit equals 1/10 gamma unit.
- 1 gamma unit equals 1/1000 milligram

Colorimetric quantitative analyses were made of urinary estrone during the course of pregnancy for 10 women. As early as the sixth week the urinary estrone level was found to be at least twice the highest level found in nonpregnant women. Large individual variations occurred but in general the highest figures were obtained when the placenta was very large and was associated with a large baby. A prompt fall of the level followed childbirth and expulsion of the placenta.

These studies are interpreted as supporting the contention that considerable augmentation of urinary estrone occurs in the course of pregnancy and that this augmentation is due to the secretory activity of the placenta. *Edward W. Goss, M.D.*

O'Connor, C. T., and Bradley J. J. Retroperitoneal Hemorrhage Complicating Pregnancy *N. England J. M.* 946 35 648.

Retroperitoneal hemorrhage complicating pregnancy is extremely rare but probably occurs more frequently than reports indicate.

One type is characterized by severe abdominal pain and shock as a result of massive retroperitoneal hemorrhage in the upper abdomen. The most frequent source of the hemorrhage is disease in the kidney and its vessels. The condition is usually fatal.

The other type, reported here for the first time, is retroperitoneal hemorrhage occurring chiefly in the true pelvis and resulting in a tumor causing dystocia and necessitating cesarean section.

The source of the hemorrhage in the case reported was probably one of the hemorrhoidal veins. Such a hemorrhage should not be evacuated; its complete absorption may take months.

Charles Rawn, M.D.

Keller M.: Ovarian Hemorrhages Caused by Nidation of the Fertilized Ovum at the Level of the Ovary (*Les hémorragies d'origine ovarienne déterminées par la nidation au niveau de l'ovaire de l'œuf secondé*) *Gyn. obst., Par.* 946 45 359.

Hemorrhages due to implantation in the ovary may cause hematomas in different parts of ovarian tissue. They may be interstitial, parenchymatous, subcortical, periovarian or in preformed cysts. They are of different age and varied extent; on rare occasions they may rupture and cause a secondary intraperitoneal hemorrhage. The intraovarian hemorrhages are due to the invasion of the chorionic villi into the capillaries and small veins of the maternal circulation; in rare cases bleeding may occur also by diapedesis in abnormal permeability of the capillary wall. If on the other hand nidation occurs on the surface of the ovary in a groove of the albuginea, intraperitoneal hemorrhage ensues. Small and repeated hemorrhages are likely to form a hematocoele in the cul-de-sac of Douglas, while more extensive hemorrhages spread in the abdominal cavity. The amount of bleeding varies considerably. It may be almost nil but often reaches 400 or 500 c.c. and in rare cases it may be as high as 2,000 c.c.

Histological studies reveal the most significant disturbances at the point where the fetal tissue is contiguous to the maternal. Here the Langhans cells attack the ovarian tissue, invading the walls of the capillaries and small veins and forming the intervillous spaces, which are filled with blood. Close to the points of invasion by ectodermal cells, extra satellites of blood can be observed as the first stages of the intraovarian hematomas; sometimes a considerable perovarian hematoma is formed which causes detachment and death of the ovum. A true decidua is not formed in ovarian pregnancy. The absence of a decidua vera makes the nidation precarious and predisposes to intraovarian or intraperitoneal hemorrhages.

In the later stages of pregnancy, i.e., after the fifth month, hemorrhages into the ovary and the fetal sac are rare occurrences and the pregnancy

may continue until term on the other hand in this stage of development there is grave danger of severe hemorrhages during surgical intervention, especially in the attempt to separate the placenta.

It has never been possible to diagnose ovarian pregnancy preoperatively all we can do is to diagnose an ectopic pregnancy in general and leave the correct diagnosis of ovarian pregnancy to the time of operation. If the operation has to be done in advanced stages of pregnancy or close to term the technical difficulties can become very serious in the attempt to separate the placenta, hemorrhages may occur which may endanger the life of the patient. In these cases marsupialization is sometimes the only safe procedure.

WERNER M. SOLMITZ, M.D.

Socias, G: Fetal Survival in Premature Separation of the Normally Inserted Placenta (Supervivencia fetal en el desprendimiento prematuro de la placenta normalmente inserta) *Bolet Soc chilena obst gín* 1946 12 102

In premature separation of the normally inserted placenta, fetal survival is an exceptional occurrence. However the problem of survival of the fetus in these cases is secondary because the severity of the condition does not warrant favoring of the fetus. Among 32 cases observed from 1941 to 1946 only 12.5 per cent of the fetuses survived.

Evaluation of the viability of the fetus may be explained by a comparison of the area of separation to the total area of the placenta. If the site of separation is near the great vessels the possibility of survival is small. Measurement of the weight of the clot is of no value as the clot not only forms on the placenta but also outside of the site of the separation.

One theory of fetal death is attributed to shock produced by histamine liberated from the traumatized placental tissue. The histamine is absorbed by the fetus and produces death mostly in premature or defective fetuses which explains death in the cases with small separation.

Madell, L. H.: The Present Status of Transfusion of Whole Blood and Its Derivatives in Obstetrics and Gynecology *Am J Obst* 1946 52 788

Blood transfusions are an essential form of obstetric and gynecologic therapy. In view of the recent advances in our knowledge of this subject, obstetricians and gynecologists have a threefold responsibility.

1 To have an ample supply of whole blood and plasma available. This can be assured by the establishment of a community blood bank such as has been suggested by the Red Cross.

2 To demand that the collection, preservation and administration of whole blood and plasma conform to the best technical standards. The adoption of the closed system vacuum technique and the use of the ACD preserving solution will meet such criteria.

3 To insure that blood or plasma administered to patients must be beneficial without reaction, and to

avoid antibody stimulation which may subsequently cause difficulties in later pregnancies or transfusions. This can be accomplished under a pyrogen free technique by the use of group and Rh compatible blood for routine transfusions of Rh negative group O blood with a low titer of isoagglutinins for emergency transfusions and of a compatible group or group O plasma with a low isoagglutinin titer when plasma is indicated.

JOHN R. WOLFF, M.D.

LABOR AND ITS COMPLICATIONS

Snoeck, J. and Rocmans, M. The Management of the So-called "Normal Delivery by the Obstetrician. Obstetrical Analgesia (Quelle doit être la conduite de l'accoucheur pendant l'accouchement dit normal." *L'analyse obstétricale* *Gyn obst., Par* 1946 45 257

This article gives a comprehensive account of all aspects of obstetrical anesthesia and analgesia. It includes an excellent detailed description of the anatomy of the central and autonomic nervous systems in their relations to the innervation and function of the uterus and to obstetrical anesthesia. Instructive illustrations are added.

The authors discuss the advantages and drawbacks of all known methods and drugs used for analgesia and anesthesia in obstetrics. Of special interest is the discussion of the different methods of producing peripheral anesthesia. This chapter includes epidural, paravertebral, and continuous caudal anesthesia, as well as the blocking of the lumbar sympathetic nerve by injection into the paravertebral ganglia, the superior or inferior hypogastric plexus, and the internal pudendal nerve.

The conclusions at which the authors arrive differ considerably from the consensus in the United States. This difference of opinion may be due partly to the fact that in France there are fewer highly and specifically trained anesthetists than in this country. In the category of inhalation anesthetics, the authors consider nitrous oxide as the only agent without any toxic side effects for mother and child. It demands a minimum of supervision and does not inhibit the uterine contractions. However it does not produce complete anesthesia, often the pain is only attenuated. Cyclopropane is quite satisfactory but it demands a highly trained and experienced anesthetist and a complicated and expensive apparatus. All other inhalation anesthetics are considered too dangerous for mother or child or both.

The groups of opium derivatives and barbiturates should be rejected altogether as they are too ineffective in small doses and too dangerous in large ones.

As to the different methods of anesthesia by blocking pain conduction either in the spinal medulla or in the peripheral nerves, the authors believe that these are still in the experimental stage and should be studied further before they are accepted as safe and effective. Of the different methods of this kind the authors prefer the infiltration of the lumbar sympathetic nerve whereas caudal anesthesia

(little known in France) seems to them to be complicated in its technique and not without risks (convulsions or circulatory collapse).

The details of this very interesting article should be read in the original. WAXNER M. SOKOLZ, M.D.

Gosselin, O.: The Management of the So-called "Normal" Delivery by the Obstetrician Not Including Analgesia and Anesthesia (Quelle doit être la conduite de l'accoucheur pendant l'accouchement dit normal. Analgésie et anesthésie exceptées) G. *ibid* Par 946, 45 35

Even if there is no anatomical obstacle or other condition which demands intervention in the interest of the mother or child, a delivery can no longer be considered normal if the duration of labor exceeds a certain time limit. 'The sun should not rise twice over a woman in labor' (Doederlein). It is no longer justifiable to maintain an attitude of purely passive expectancy in prolonged labor. The danger is twofold: infection after the membranes are ruptured, and asphyxia of the child by tetanic contractions of the uterus. No delivery should be termed "normal" which has not been completed within 10 or 12 hours after rupture of membranes. The main reason for prolonged labor in "normal" cases is disturbance of uterine contraction and dilatation of the cervix, caused either by spasticity and hypertony of the cervix, or by weakness and inertia of the uterine muscle. The dilatation of the cervix is not a passive phenomenon due to the pressure of the bag of waters on the cervix, but rather an active process caused by the traction of the spiral fibers of the corpus on the fibers of the cervix. The "physiologic delivery" is due to the harmonious interaction between contraction of the upper and relaxation of the lower part of the uterus.

Prolonged labor due to spasm of the cervix should be treated by rupture of the membranes and with antispasmodic drugs. A number of outstanding French obstetricians rupture the membranes routinely in all cases when the cervix is dilated to a cm. and others at a dilatation of 4 or 6 cm. Objections against this routine can be made for two reasons, i.e., increased danger of bacterial invasion, and danger of prolapse of the cord. However, these dangers seem to be negligible as the saprophytic germs of the vagina seldom cause infection, and prolapse of the cord is of rare incidence (34% in a series of 575 cases).

The antispasmodic generally used in France is called spasalgine. It is a mixture containing pantopon (0.05 gm.), papaverine (0.05 gm.) and atropine (1 mgm). Many outstanding men (Kreiss, Voron, Pigeaud) give it routinely in all cases. If necessary it can be given several times in intervals of 30 minutes without danger to the mother and child.

Prolonged labor due to the opposite disturbance, namely weak contractions, should be treated by oxytocin. In contrast to the opinion prevailing in the United States, the French authors deem it permissible to use pituitrin also in the second stage of labor provided that it is given in very small doses (2 inter-

national units) and under close supervision. In some cases, it is advisable to combine the pituitrin with an antispasmodic. WAXNER M. SOKOLZ, M.D.

Lévy-Solal: Anomalies of Uterine Contraction (Anomalies de la contraction utérine) *Rev. fr. gyn. obst.* 1946 41 225.

Extreme prolongation or even arrest of labor is often seen in cases of functional uterine dystocia. In the studies of uterine contraction, particularly by means of external hystero-graphy, a great deal may be learned in the cases of hypercontractility one sees either (1) inertia or functional insufficiency of the uterus or (2) an excess of contractions, either intermittent or tonic contractions.

The hystero-graph is composed essentially of a large pneumatic tube and an oscillograph. The tube held in place by an inextensible belt is inflated under a known pressure; the excursions transmitted from the tube are recorded on a drum which revolves at a known rate of speed. Normal contraction appears as a line ascending sharply then a plateau more or less notched and then a line descending slowly to the base line. The height of the peak is a measure of the maximal power of the contraction (or uterine tones) and the line its duration. Labor contractions are represented by the area bounded by the base line and the arc.

Intermittent and involuntary uterine contractions become painful during labor. The pain appears somewhat in advance of the contraction and disappears shortly after it. It is only perceptible above a certain threshold; this explains why the mild contractions, such as those which follow immediately after the expulsion of the fetus, pass unperceived both by the woman herself and the obstetrician.

The duration of the contractions is from 10 to 30 seconds. The contractions follow a rhythm which varies not only from one patient to another but also in the same patient starting with a duration of 10 minutes and ending with a duration of 3 minutes. Each contraction is followed by a period of repose, the state of tension of the uterus or its absence being designated by either an arc or a horizontal line (Graph 1). Physiologically, the uterine tones are always the same, varying only if the uterine capacity is suddenly changed as, for example, by the rupture of the membranes. Pathological variations of tones are observed chiefly in the hyperkinetic uterus. The persistence of pain during the period between contractions is a sign of poor muscular relaxation. In cases of inertia or functional uterine insufficiency one sees undulations and shortening of the base line, and the intervals are very long, lasting from 15 minutes to even several hours (Graph 2). Intermittent contractions show up as a successive series of similar waves with the common characteristic of a constant return of the peak to its base line of departure as long as the contraction retains its forcefulness (Graph 3). One sometimes sees a series of unremitting ineffective contractions (Graph 4); this state of contraction can evolve following two eventualities: (1) after a

Fig. 1. (Levy Solal)

more or less protracted period of successive spikes (Graph 5) as may be observed following the administration of barbiturates and (2) between maximal contractions irregularly placed when the intervening quiet period is represented by a horizontal line at the lowest point. In this case the decrease in the severity of labor is due not to a state of inertia or to the effacement of the contractile wave but to an elevation of the tonus (Graph 6). This latter state, due to muscular overwork, provokes an arrest of labor. It does not represent uterine inertia and oxytocics should not be employed. Rather antispasmodics or even morphine should be used to diminish the resistance due to muscular hypertonicity to give each contraction its full value. When the tracing discloses a permanent elevation of the muscular tone then spinal anesthesia is indicated; thus the contractility is abolished and the retraction of the uterine body and its tonicity are augmented.

These anomalies, i.e. functional insufficiency or excess of contractions, may be due to various causes: there may be congenital central or autonomic nervous system derangements or there may be fibroids

or adhesions of the uterine musculature which breaks up the contractile wave before it reaches the base of the uterus. In general, however, the neuromuscular system is normal and the contraction is vitiated secondarily. This is not only a reaction of the uterine muscle. It may also be due to an abuse of hypophyseal extracts, or to repeated and prolonged mechanical excitations by obstacles difficult to overcome. Also these difficulties follow more or less tardily after a phase of regular contractions.

The obstacle may be due to either (1) resistance of the soft tissue, the inferior segment or the uterine collar, or (2) fetal disproportion. The inferior segment may be either rigid or supple. The neck can be the site of diverse alterations which add to the complication of anatomic malformations or inflammation involving the normal course of effacement and dilatation often produced by scar tissue secondary to the intemperate use of caustics. As for the fetal head it may be imperfectly adapted even to the shape of the uterus and cannot descend without distending the inferior segment: this is seen particularly in forehead and shoulder presentations. An undis-

closed osseous dystocia may also condition a poor presentation. In these secondary anomalies the reaction by inhibition or true atony is rare. It is the contracture that one sees most often.

However all of these anomalies of contraction due to various mechanisms have the same result: extremely slow progression and even arrest of dilatation—in inertia because of weakness, infrequency of contraction, lengthening of intervals in the states of contraction, because of constriction and stretching of all the uterine fibers and finally in the states of hypertonicity because of uterine retraction which constricts the fetus.

Physiopathological difficulties are manifest clinically in the following forms:

1. Functional insufficiency. This occasionally persists from the start to the finish of labor; it generally is modified in a eutocic sense or it is complicated by difficulties of malcontraction. This can be determined clinically or by graphic exploration. Indeed, when inertia exists in a pure state, one sees labor desperately prolonged. The contractions are feeble, of short duration, painful, placed far apart, even in spite of perfect engagement of the head and perfect conformation to the inferior segment. Labor can sometimes last for days if means for establishing a normal pace are not employed.

2. True muscular dystocia in labor. This is due to contracture. It can be mild or severe; it can involve the whole organ or can be localized in certain zones.

The states of mild contracture are observed in only particular circumstances: the membranes are generally intact and the uterine body struggles against the inferior segment which resists more or less. But little by little the weak musculature of the inferior segment and the neck give way before the pressure of the uterine body. The cervical canal opens passively either by pressure from the bag of waters or from the fetal prominence. That is the rule. But these are rare cases which one cannot foresee in which the muscular elements of the cervical region resist longer and more abnormally in the course of the period of dilatation.

The clinical syndrome which indicates this struggle is also typical. The woman essentially has lumbar pain. On palpation the uterus is uniformly hard and this hardness persists a long time without relief. The heart sounds are muffled and the uterine souffle is exaggerated to auscultation. On touch the inferior segment is tight resistant, and painful often it is poorly formed. The neck can either remain thick when the presenting part is high or on the contrary soft when it comes in direct contact with the outlet, but at the moment of a contraction this is checked and it seems as though it were bounded by an iron band. This syndrome has received various interpretations, the most current one being an active contraction of the uterine neck during labor.

Hystero-graphic films have shown that this cervical rigidity corresponds, in fact, to a state of uterine subcontraction. Indeed a uterus does not contract except when it reacts in coming up against an ob-

stacle to its dilatation. It is this obstacle often not apparent that one should look for.

In the cases of strong contracture the cause of arrest can be found in factors which alter the normal functioning of the neck or of the lower portion of the uterus. This can perhaps be an abnormal adherence of the membranous pole around the uterine outlet which prevents the normal progress of ablation of the inferior segment. A relatively simple procedure is to break these adhesions with the fingers or better to rupture the membranes. The inferior segment regains its elasticity and dilatation progresses rapidly. This condition may be called agglutination of the neck, the origin of which one frequently finds to be an alteration of the neck by therapeutic caustics or endometrial inflammation. One recognizes this anomaly when it is difficult on vaginal examination to outline the orifice of the neck, especially when the thinness of the inferior segment, pressed tightly on the presenting part, reveals the existence of a complete dilatation. It is important to search carefully for the site of the depression (more or less distinct) which discloses the presence of the external orifice of the neck, then to introduce the tip of the index finger or a catheter so that the cervical obstacle can be lifted and the dilatation can progress rapidly.

There are indeed cases in which an excess of liquid, important because of the extreme distention that it can produce at the base of the uterus, deprives the inferior segment and the collar of all its pliancy. The artificial rupture of the membranes permits the uterine muscle to regain its normal contractility.

Sometimes one can find no apparent cause for the phenomenon of contracture and authorities have shown the influence of antispasmodics which, administered at the onset of accidents, are capable of cutting down the cervical resistance and regulating the contractions. These ideas are significant from the point of view of treatment.

In addition to these phenomena of contracture due to a cervicosegmental obstacle easy to correct, there are others in which the obstacle is more serious and the contracture if left alone, can assume a very grave character. The difficulties coincide generally with the onset of premature rupture of the membranes, but it is not this rupture which causes the difficulty. This anomaly of contracture is revealed by the clinical pace of labor. The pains are lumbar and unremitting continuing even through the intervals between contractions. The woman is seen to suffer even when the uterus is apparently relaxed. This impression corresponds, as was shown in the hystero-graphic curves, to an elevation of tones to the level of the pain threshold in the intervening period.

However, the general syndrome which accompanies the painful phenomena is perhaps as typical as the pain itself. The women are agitated, complain constantly vomit, and present a rapid pulse.

On palpation two syndromes can be observed: 1. Following sufficient labor the presentation which was high has descended into the inferior segment. It strikes an obstacle there and progression

ceases. The uterus is contracted on the superior part of the fetus and presses itself upon it, it stretches the inferior segment. The permanent hardness of the muscle due to the contracture contrasts with the thinning by distention of the inferior segment.

2 The uterus contracted from the outset, tightly bands the fetus over which it is molded. The inferior segment is malformed the presenting part is high. The fetal head which is the agent of the transmission of forces, instead of progressing remains completely imprisoned in the interior of the uterine cavity. The state of the uterine neck is variable to touch sometimes the dilatation is very advanced at other times it remains stationary at about 2 to 5 francs. When the fetus is entirely trapped in the contracted uterus there is anywhere from a finger tip to 10 cm. of the external orifice and one can perceive the presenting part above the ring of stricture which marks the inferior limit of the corpus uteri.

When the head reaches the ring it appears like a pendulum in the inferior segment which it does not touch and the shoulders are supported above the zone of strangulation a sensation of unusual resistance occurs when one attempts a forceps extraction or an extraction with a basiotribe.

This state of contraction does not always persist at a given moment the uterus may appear to relax. However this relaxation is not much better for it denotes muscular fatigue. In fact the hysterograph discloses a permanent elevation of uterine tonicity. If treatment is not given immediately the condition becomes much worse—in addition to hypertonicity capable of responding to agents modifying the uterine muscle fibers there is a state of irreducible retraction corresponding to histological lesions which in extreme cases appear as interstitial edema. This infiltration occurs not only at the neck but also more or less throughout the entire inferior segment. It is an edema which at first is soft and appears to harden somewhat as the syndrome evolves. On palpation it gives the sensation of leather filled with fat. Couvelaire has shown that the element of infection plays a considerable role not only in the appearance but also in the persistence of these cervical alterations. The contamination of frequent examinations, the suppression of the anti-infection barrier set up by the bag of waters, and the abnormal duration of labor after arrest of the presenting part explain the state of these alterations easily confirmed by microscopic examination of specimens of the neck which show all stages from the leucocytic infiltration to microbic penetration. These anatomic lesions explain the almost absolute impossibility of the neck to dilate by normal mechanisms. The neck does not dilate—it ruptures. It is in these conditions that one sees transverse fissures or even a spontaneous circular amputation, and these accidents can progress to the point of uterine rupture or at least to favor serious amniotic infection.

The difficulties are inherent in the general etiologic conditions that have been studied. Indeed behind these same contractures one usually sees two fre-

quent causes the congenital malformation and the irritation of the uterus provoked by a bad position or even by an irregularity of the fetal head or some times by untimely intervention.

This irritability has been studied on a fresh specimen which was removed en bloc by hysterectomy. Uterine contraction is dependent on an autonomic intrauterine system as well as on the lumbar spine. In looking over the specimen the authors noted the presence of spontaneous intermittent contractile rings. The idea of opening the uterus and stimulating it with a stylet was conceived. When the irritation was intermittent it was seen that each time the tip of the stylet was touched to the muscle, circular contractions occurred contractile rings starting at the periphery and converging toward the point of irritation. When the stimulus was continued the uterine muscle froze as it were into a solid contraction (tetanic) which relaxed almost immediately on withdrawal of the stimulus.

The constriction rings occur at various levels of the body of the uterus. One sees them most often at the junction of the body and the inferior segment, more from autonomic than functional causes. In the habitual cephalic presentation this region corresponds to the furrow of the neck of the fetus.

In breech presentations the muscular constriction forms preferably at the level of the popliteal fold. In transverse presentations, when the head and shoulders are in the inferior segment, the ring can pass as a sling on the neck and the thorax of the fetus.

Clinically the essential signs of the preceding form are the same as those found after premature rupture of the membranes the same permanent character of the pain radiating to the lumbar region and as in total contracture, the extreme slowness of labor with precocious appearance of the fetus.

Several clinical signs permit differentiation of these two forms. By inspection and palpation one can often discover a notch on the uterine margin which persists even during contracture in fact this notch is usually discovered during intervention and the uterine wall forms a cul-de-sac above this notch. Reorientation of the fetal head usually corrects this situation otherwise there is a rigid retraction which is of serious import to both mother and fetus. Two syndromes may be associated with this situation either pure inertia or inertia with contraction.

It is emphasized that uterine atony and rigidity are always secondary and the primary cause should be investigated from the standpoint of the uterus pelvis and fetus. The pelvis may have a narrow superior outlet or there may be a face presentation. In these cases a cesarean section is indicated. If dystocia is purely uterine i.e. dynamic, medical management with antispasmodics is indicated. Membranes are ruptured when the dilatation has attained 4 or 5 cm. then quinine or posterior pituitary extract may be used. In this way cervical resistance is abolished and an easy intervention with an engaged head and complete cervical dilatation is possible. Anti

spasmodics have been found to diminish the abnormal duration of hypercontractility and permit normal relaxation between contractions. Thus, severe uterine retraction with rupture, amniotic infection, endometrial gangrene and peritonitis are avoided.

Among 61 cases reported 47 physiological deliveries resulted following the use of antispasmodics. Thirteen cases resulted in intervention 6 were forceps deliveries following cervical incisions anteriorly and posteriorly 2 were spontaneous deliveries following cervical incisions, 2 were cesarean sections and 3 were managed with the basotribe. There were no maternal deaths but 7 fetal deaths. It is concluded that antispasmodics have transformed the management of problems of dystocia. Results might have been better had intervention following the use of antispasmodics in some cases been earlier the optimum time seems to be when the dilatation remains stationary after 2 hours, although fetal distress usually begins after 12 hours. Rupture of the membranes should be carried out when there is a permanent tension when there is adherence of the inferior part of the fetus, or when no other reason for nonengagement has been found and the bag of waters rests on the cervical orifice. There should always be at least a 5-franc opening of the canal before rupture is attempted.

With regard to the use of antispasmodics, a first series of 2 or 3 injections of spasalgine at one-half hour intervals is employed. This usually suffices to regulate the contractions and abolish uterine tonus without employment of a second series. If dilatation is stationary after ten hours, either cervical incision or section should be done. In primiparas, in the presence of a large fetus or after premature rupture of the membranes, intervention should be done earlier.

PHILIP B. CHASE, M.D.

Reid D. E.: The Treatment of Prolonged Labor with Extract from the Posterior Lobe of the Pituitary Gland. *Am J Obst* 946 51 719.

Prolonged labor dependent on uterine inertia and associated with cervical dystocia, is a syndrome occurring with rare exception only in primiparous women. Such exceptions are not due to cervical dystocia per se, and may occur in the "dangerous multiparas" with definite or borderline cephalopelvic disproportion. The author administered extract from the posterior lobe of the pituitary gland to 1500 patients who exhibited any degree of uterine inertia during their labor. Uterine inertia exists when progress during labor ceases. The initial dose of this drug is usually 1 minim. The dosage is increased up to 4 minims at a single dose at from 30 to 45 minute intervals in an attempt to stimulate uterine contractions. Usually cervical dilatation will ensue with the smaller doses. The total dose in a given labor is usually from 1 to 4 minims, but doses from 5 to 9, 10 to 15, and even of 15 minims plus were administered during a single labor.

However if no effective uterine contractions or progress has been obtained after 1 to 4 minim doses

have been used (which will cover a period of from 1 to 3 hours) it seems reasonable to discontinue the drug and turn to other means of completing labor. Procrastination from that point on will only add further hours of labor and an increased fetal mortality.

With the use of this drug there have been no cases of ruptured uterus or extensive birth canal trauma in this series. The incidence of prolonged labor has been reduced to the low figure of 2 per cent in the clinic patients. The need for midforceps operations in the clinic patients was reduced to 0.5 per cent. The need for Duhrssen's incisions was small. Some degree of intrauterine asphyxia accompanies normal labor. In this series it was 0.33 per cent.

Prolonged labor contributes materially to an increased fetal mortality. This is true particularly if the labor is more than 40 hours in length. Fetal mortality in the clinic patients with prolonged labor was 11.65 per cent a figure which usually accompanies such cases. Intrauterine asphyxia was the most frequent cause of fetal death. JOHN R. WOZNY, M.D.

Mujica, H.: Internal Version in the Angel Custodio Santhomas Maternity Hospital (La versión interna en la Maternidad Angel Custodio Santhomas). *Bolet Soc chilena obst gine* 946, 57

Among 1533 deliveries over a 5 year period, internal version was performed in 422 or 27.5 per cent, of the versions, and was 3 times as common in the multiparas as in the primiparas. A comparison between the incidence of versions, forceps deliveries and cesarean sections showed that versions were carried out in 2.78 per cent, forceps in 4.21 per cent, and cesarean sections in 1.24 per cent of the cases. Throughout the 5 year period the use of forceps increased and the use of versions decreased the number of sections remained about the same.

Of the indications for versions, fetal distress accounted for 31.50 per cent, transverse presentation for 27.48 per cent, prolapse of the cord for 12.79 per cent, maternal exhaustion for 10.18 per cent, stoppage of labor mechanism for 4.97 per cent, prolapse of the superior extremity for 3.55 per cent, deformed cephalic presentation for 3.08 per cent, and twins, infection, excessive size of the fetus, dystocia of the cervix, and uterine rupture accounted for the remaining 3.31 per cent.

The complications which were seen following versions were as follows: perineal tears (22.51%) of which 28 per cent were 1 degree 3.79 per cent of 2 degrees, and 0.71 per cent of 3 degrees; cervical tears (20.61%); vaginal tears (6.39%); vulvar tears (0.94%); tears of the lower segment (2.84%); hyper-tonicity of the uterus (6.16%); uterine inertia (4.30%); retained secundines (7.34%); rupture of the cord (1.65%); transverse presentation of a second fetus (0.23%); retention of the aftercoming head (5.68%); locked arm (8.29%); anemia (3.60%); obstetrical shock (0.94%); and anesthetic syncope (0.33%).

The puerperal complications were as follows: simple endometritis (4.73%); purulent endometritis

(4.97%) infection of an episiotomy (3.60%) a febrile puerperium (0.47%) abscess of the abdominal wall (0.23%) putrid endometritis (0.69%), genital gangrene (0.47%) puerperal septicemia (0.47%) phlebitis (0.23%) subinvolution of the uterus (0.93%) anemia (0.47%) and late hemorrhage (0.23%).

Two-fifths of the patients with complications required the following treatment: repair of the canal (27.25%) placenta extraction (9.47%) dilatation and curettage (3.31%) colpotomy (0.23%) blood transfusions (1.65%) suture of the lower segment (1.65%) biopsy of the cervix (0.23%) delivery of the second twin (0.23%) forceps on the aftercoming head (0.23%) craniotomy (3.08%) and tamponade (0.46%).

Ether given by intravenous drip was used in 97.63 per cent of the cases.

The maternal mortality was 2.07 per cent and the infant mortality was 14.22 per cent; the morbidity was 25.35 per cent. ARTHUR F. CIPOLLA, M.D.

Kahanpää, V.: Cesarean Section with Special Emphasis on the Transverse Transperitoneal Incision (Ueber den Kaiserschnitt mit besonderer Berücksichtigung der queren transperitonealen Schnittführung). *Ann. chir. gyn. fenn.* 1946 35: 157.

This is a report on a series of 825 cesarean sections. The indications were contracted pelvis in 49.6 per cent, eclampsia and similar conditions in 19 per cent, placenta previa in 7.5 per cent and others in 23.9 per cent. Three hundred and eleven of the women were subjected to the transverse isthmus section. A comparison of the longitudinal (cervicocorporal or lithomolgitudinal) and the transverse incisions shows that the latter is preferable: it is easier technically, the hemorrhage less and the operation time shorter. There were also fewer postoperative complications. In no instance did uterine rupture occur in subsequent deliveries.

WERNER M. SOLMITZ, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Klein, J.: The Relationship of Maternal Weight Gain to the Weight of the Newborn Infant. *Am. J. Obst.* 1946 52: 574.

Most physicians who supervise prenatal care caution their patients against excessive weight gain during pregnancy. Their reasons for doing so are multiple. It is the opinion of many that the size of the fetus may thus be controlled. Prevention of overgrowth of the baby, especially in the presence of a pelvic contracture, would reduce the incidence of disproportion with its attendant hazards.

A series of 367 cases was studied statistically by the author to determine whether any relationship existed between the maternal weight gain and the weight of the newborn. In this group of cases, 408 primiparas and 159 multiparas were delivered of 282 male and 285 female infants. The heaviest baby

weighed 10 lbs and 7.25 oz at birth; the lightest 5 lb and 4.5 oz. One mother who had lost 3.25 pounds during pregnancy gave birth to a girl weighing 5 lb and 14 oz. The patient who had gained the most weight, 48.25 pounds, was delivered of a girl weighing 6 lb and 5.5 oz. The average maternal weight gain for the series was 31.05 pounds and the average weight of the newborn was 7 lb and 6 oz.

No correlation was noticed between the maternal weight gain during pregnancy and the weight of the baby at birth. The average birth weight of the males exceeded that of the females. There is no relationship between the age of the mother, her weight gain during pregnancy and the weight of the newborn infant. Although the average maternal weight gain and the average weight of the newborn of multiparas were greater than those of primiparas, the differences were slight and of no significance.

JOHN R. WOLFF, M.D.

NEWBORN

Repetti, M.: Fetal Erythroblastosis (Soll. eritroblastosis fetale). *Fed. gyn.* Genova 1946 41: 3.

The author describes 2 cases of fetal hydrops, and 1 case of acute congenital icterus. In fetal hydrops the fetus is born prematurely as a stillbirth or dies immediately after birth. Heredity plays a part and may alternate with successive deliveries of fetuses with icterus. The liver and spleen are enlarged and there is an increased number of immature red blood cells and white blood cells. Foci of hematopoiesis in the liver, spleen, placenta, and other organs are evident. The amniotic fluid is increased in amount and has a yellow color.

Acute congenital icterus is often fatal and is characterized by a marked pallor of the skin with a short continuation of the intense jaundice. The liver and spleen are enlarged and focal embryonal hematopoiesis is revealed by masses of erythroblasts in various states.

Erythroblastosis of the newborn is characterized by an intense anemia, hepatomegaly and splenomegaly with increase of the nucleated red blood cells and reticulocytes. Foci of erythropoiesis are also seen.

Although these processes appear to be different they are related. Fetal hydrops is the gravest, congenital icterus is intermediate and hemolytic anemia of the newborn is the least grave condition. The incidence of these conditions is much higher than was formerly believed.

Other conditions which produce a similar picture and therefore must be considered in the differential diagnosis are as follows: syphilis, sepsis, producing anemia, hemorrhagic disease of the newborn, congenital malformation of the biliary tract, and physiological icterus of the newborn.

Not only has the Rh factor been found as the etiological cause of these conditions, but the placenta is the route by which the antigens pass, although sensitization of the newborn may take place by intra-

muscular injection of Rh positive blood. The foetal-Rh antigen is also present in mother's milk and may sensitise the newborn by its ingestion through the intestinal tract therefore this milk is contraindicated.

The treatment is transfusion with Rh positive blood and the administration of Vitamin K.

ARTHUR F. CROCOLLA, M.D.

MISCELLANEOUS

Splavack, M: The Anatomic Peculiarities of the Human Umbilical Cord and Their Clinical Significance *Am. J. Obst.*, 946, 5: 387

The author reports her observations of the anatomic peculiarities of the human umbilical cord. Twenty five specimens were examined grossly for the presence of 'valves', folds, and other peculiarities. Thirty were studied microscopically with special attention being given to the blood vessels. All these cords were from babies born alive. Cords from dead babies were utilized for the search of nerve tissue.

The umbilical vessels were found to differ anatomically from other blood vessels in several essential ways. True valves were not present. The presence of folds and nodules (nodules of Hoboken) were

noted in the arteries and semilunar folds in the veins. The elastic tissue of the umbilical vessels varies from that seen in other vessels of similar size. The arterial media is strongly developed and its powerful contractions are ascribed by some authors to the spiral and snail-like course of its muscle fibers. Vasa vasorum and adventitia were not present. There is a delicate connective tissue which contributes to the sponginess of the vein.

The author demonstrates for the first time the presence of a nervous apparatus within the umbilical vessels.

Splavack points out the clinical application of the value of not ligating or tying the umbilical cord until its pulsation has ceased. She reviews the reports demonstrating the amount of blood that can be drained from the placenta into the fetus by adopting this dictum, and reasons that this occurs because the anatomic peculiarities of the umbilical vessels are such that the arteries have greater contractile power than the veins and compression of the placental vessels will lead to a contracting, narrowing, and obliteration of the arterial cord, with an increase or dilatation of the umbilical vein. Thus the outflow of the blood from the baby to the placenta is hindered while the return flow is augmented.

JOHN R. WOLFF, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Söderlund, G. Four Cases of Tuberculosis of the Kidney. *Acta chir. scand.*, 1946 94 470

Four cases of renal tuberculosis are reported by the author because they are interesting from the standpoint of diagnosis. Indications for operation or pathological findings.

A 42 year old man was operated on in 1930 for a rather extensive hydronephrosis of the left side of a horseshoe kidney. Pyelolithotomy was performed. In 1944 an extensive tuberculosis of the right half of the kidney was diagnosed. The involved portion was removed and the patient was discharged cured.

In a 20 year old girl tubercle bacilli and pus were found in the urine, and urographic studies revealed an extensive tuberculous process in the left kidney and also a few irregular cavities in the involved kidneys considered to be also of a specific character. Two years later the urine from the right kidney appeared to be normal and the cavities in the involved kidneys were no more visible after retrograde pyelography. The tuberculous left kidney was removed and the patient was discharged cured.

In a woman age 45 with cystitis of 3 years duration the urine was found to contain pus and tubercle bacilli. Urography revealed an extensive tuberculosis of the right kidney and a rather large hydronephrosis of the left kidney. The urinary bladder was contracted. The nonprotein nitrogen was 100 mgm per cent. After insertion of a retention catheter the nonprotein nitrogen gradually diminished to 36 mgm per cent. The tuberculous right kidney was removed and the bladder gradually expanded.

A woman age 35 had had periodic attacks of fever without local symptoms for 10 years. Urography and urine examination failed to disclose any pathology of the urinary tract but 3 years later a congestion of the upper pole of the left kidney and a displacement of this kidney downward and in a lateral direction were found. Nephrectomy was performed and a large cavity was found in the upper half of the removed specimen. Colon bacilli were demonstrated in the pus of the cavity which was not communicating with the renal pelvis. The histological examination disclosed the presence of tuberculous. The patient made an uneventful recovery.

JOSEPH K. NARAT, M.D.

LeComte R. M.: Perinephritis and Perirenal Abscess. *J. Urol. Balt.*, 1946 56 636.

The author's study is based on records of 28 patients which contain fairly complete data. They have been culled from some 9,600 odd cases of real or suspected urologic disease encountered over a period of 25 years an incidence of about 0.3 per cent.

Eleven of the 28 patients were in the primary or uncomplicated group all of these recovered. Eight of

the 17 patients with secondary or complicated disease died a percentage of 46.5 per cent. The mortality for the entire group was 28.5 per cent. All of those who died had renal infection which in 2 probably originated from prostatic obstruction in 1 patient the abscess probably developed as a result of extension from a ruptured posterior urethra torn in a poorly performed internal urethrotomy in 1 patient there was a left renal stone and acute bilateral pyelonephritis with multiple small abscesses in 1 patient following puerperal sepsis, the condition was discovered at autopsy and a pelvic as well as a perirenal abscess was found in 1 patient had active pulmonary and renal tuberculosis. The 2 other patients who died had acute renal infection of undetermined anatomic origin. The former died from sepsis and shock following the too thorough exploration of an infected kidney in searching for a stone, the latter died from pulmonary tuberculosis. The time intervening between operation and death varied from 1 day to 3 months. All but 2 of the 17 patients with secondary cases (1 with vertebral disease and 1 with appendical abscess) had urinary infection of some sort ranging from hydronephrosis with or without stone and obstruction, to prostatic abscess, urethral strictures etc.

On x ray a mass was observed in 6 of 10 patients. The spine was concave towards the side of the abscess in 7 patients, and convex in 1 of the 10 in whom this finding was set down. The psoas shadow was obliterated on the involved side in 6 patients, on both sides in 1 patient, and was indistinct in 1 of 8 patients. The pyelogram was recorded in 13 cases the kidney was considered to be normal in 6 was reported as deformed without characteristic change in 2 as showing evidence of external pressure in 3 and of hydronephrosis in 2 patients, each of whom had ureteral obstruction. The kidney was displaced laterally in 2 and medially in 2 of 4 cases. It was fixed in 1 of 2 instances in which this feature was checked.

The multiplicity of possibilities as to pathogenesis and mode of invasion has led to a somewhat confusing classification and terminology based on points that often cannot be determined with certainty even at operation or autopsy. The author's preference is to consider the basic lesion as a perinephritis nonsuppurative or suppurative and to designate the suppurative form with definite abscess formation as perirenal despite the objectionable impure composition of the word (Simeone). This avoids the confusion due to the similarity in spelling and sound of the words, perinephritic and perinephric.

Bacteria may reach the perinephrium by metastasis or as heretofore set forth, by extension from inflamed nearby organs. A perirenal abscess may occur from metastasis, too if a hematoma from traumatism has occurred in the perinephrium and if bacteria circulating in the blood lodge and multiply in it. The point of origin is immaterial if renal or other complicating

ly disturbing the abscess wall. Failure to drain second ary abscesses may lead to delayed healing which will require a second operation

If no frank pus is encountered and the perirenal fat is found to be hard and hemorrhagic, a thorough exploration of the perinephrium should be done especially behind and at the upper pole of the kidney

If a renal lesion is known to exist beforehand or is found at operation it is generally better to be content with drainage of the abscess especially if the patient is markedly septic, leaving the primary renal difficulty to be cared for later. A secondary nephrectomy is often difficult and somewhat hazardous but is perhaps less dangerous than the spreading of infection from extensive handling of a kidney in the presence of extensive suppurative perinephritis.

JOHN A. LOEY M.D.

Munger A. D.: Renal Surgery *J Am Med Ass* 1946
132 675

The author urges greater conservatism in renal surgery. Too often the kidney is sacrificed when it can be readily saved by a conservative procedure. Conditions for which nephrectomy is performed are frequently limited to only a small portion of the kidney substance. Resection of only the diseased portion of the organ is the preferable procedure.

In the hands of many surgeons the only operative procedure for hydronephrosis is nephrectomy. Surgical correction is for the most part a perfectly logical and feasible operation. Protective splinting with adequate and prolonged intrapelvic drainage is an absolutely necessary procedure in plastic correction of the renal pelvis.

Hydronephrosis is not uncommonly a bilateral disease and the removal of a kidney for hydronephrosis is not infrequently followed by the development of a hydronephrosis on the opposite side.

About 70 per cent of diseases requiring surgical intervention and congenital in origin are amenable to conservative surgery. Total nephrectomy for hydronephrosis should be performed only when it has been demonstrated that the drainage system of the kidney is completely destroyed and beyond recovery.

When ischemia occurs in a greatly altered area of renal tissue as a result of ligation of a renal vessel to relieve pyeloureteral obstruction the author recommends resection of the ischemic area to prevent septic necrobiosis.

If the urinary passages are opened in a partial resection prolonged drainage of the pelvis is indicated to prevent fistula formation.

FREDERICK A. LLOYD M.D.

Ortega F. E. Indications for Nephropexy (Las indicaciones de nefropexia) *Arch esp. urol.*, 1946
3 174.

The mere existence of an abnormally movable kidney does not constitute an indication for nephropexy unless there is interference with pyeloureteral evacuation. Alterations in the region of the kidney can be easily detected with pyelograms. All authors

generally agree that without a specific indication nephropexy should not be performed as a supplementary operation after pyelotomy or nephrotomy. Pyelograms should be taken in the horizontal as well as in the erect position of the patient. Serial cinematographic pictures may furnish valuable information. Pyeloscopy as advocated by Legueu has not found many adherents.

Even if the kidney can be palpated and the patient complains of pains in the renal region conservative treatment is advisable if pyelographic findings are negative. In some cases the decision is difficult to make. In many instances in which torsion of the ureter by a ptotic kidney is suspected dilatation of the renal pelvis supplemented by proper medication and a dietary regimen may furnish relief. Nephropexy may easily be discredited unless strict indications are observed. JOSEPH K. NARAT M.D.

BLADDER, URETHRA, AND PENIS

Castro E. P. Vesicoureteral Reflux (Concepto actual del reflujo vesicoureteral) *Arch esp. urol* 1946
3 122

Vesicoureteral reflux in the majority of cases must be considered as a phenomenon caused by a defective synergism of ureterovesical dynamic factors. Such conditions may be created by an irritation of the muscular layer of the urinary bladder and an alteration or retardation of the transmission of reflexes which is responsible for alternating tonokinetic phases of the bladder and ureters.

According to extensive questionnaires a reflux is observed in cases of malignant but not benign lesions of the bladder. This may be explained by the assumption that malignant neoplasms create special reflexes. The author's experience does not correspond to that mentioned in the statistics as he observed a vesicoureteral reflux also in cases with non-infiltrating neoplasms.

Hypertrophy of the prostatic gland was not considered as an important factor in the creation of the vesicoureteral reflux until the introduction of cystographic studies. As a matter of fact reflux occurs in from 4.7 to 18 per cent of all cases of prostatic hypertrophy. The mechanism of production of such reflux has not been completely elucidated but the increased intravesical pressure seems to be an important factor. In addition to such passive factors as mechanical obstruction an active factor is the form of a disrupted ureterovesical synergism enters into play.

An obstruction of the neck of the bladder may be responsible for the origin of a diverticulum of the bladder and also for a concomitant reflux.

A frequent coexistence of vesicoureteral reflux and tuberculosis of the excretory organs has been observed. A transurethral resection of the neck of the bladder performed at an early stage of the condition may relieve the reflux accompanying tuberculous cystitis.

The author reports 19 cases of ureterovesical reflux. JOSEPH K. NARAT M.D.

Molina, L. R. and Estarellas R.: Instrumental Trauma following Cystostomy (Herida instrumental en un cistostomizado) *Rev. argent. urol.* 1944, 3: 441

As the first stage of the surgical treatment of an adenoma of the prostate gland, a cystostomy was done on a 37 year old man. One month after the operation the family physician tried to eliminate an obstruction of the drain. The patient experienced severe pain and the following day was admitted to the hospital. The examination showed that fecal matter not urine was escaping from the drain and between the drain and the wall of the fistula. Three hundred cubic centimeters of clear urine were evacuated through a urethral catheter. The bladder was irrigated with a solution of mercury oxychloride, but the injected liquid did not escape through the hypogastric drain. This observation proved that the bladder was occluded and that the drain in the hypogastric region was communicating with the intestines and not the bladder. The drain was withdrawn, and a curved probe was introduced through the urethra and brought out through the suprapubic fistula. A retention catheter was placed into the cystostomy opening. An antiseptic solution injected through the urethral catheter escaped through the Pessier catheter.

After insufflation of the urinary bladder with air and the injection of an opaque medium, the relations between the cystostomy, the bladder and the small intestines were visualized by means of roentgenograms. Apparently an adhesive plastic peritonitis was responsible for the connection between an intestinal loop and the anterior wall of the bladder. The circumscribed peritoneal reaction apparently prevented more serious complications.

JOSEPH K. NARAY, M.D.

Pierini, A.: Traumatic Rupture of the Bladder and Posterior Urethra. Four Observations (Ruptura traumática de la bota y uretra posterior. A propósito de 4 observaciones) *Bol. Acad. argent. ur.* 1946 30: 64.

The author reports 4 cases. The first was that of a man who sustained a fracture of the left iliopectineal branch of the pelvis which led to a rupture of the posterior urethra. The second was that of a woman with a vertical fracture of Malgaigne's type with extraperitoneal rupture of the bladder. The third patient was a 15 year old boy with a fracture of the pelvis and signs of an extraperitoneal tear of both the bladder and the posterior urethra. The fourth patient, a man 37 years old, also had an extraperitoneal tear of both organs, which had been caused by a fracture of the pelvis.

Extraperitoneal rupture of the bladder usually involves its anterior aspect but occasionally the trigonum or the posterior portion may be torn. Such injuries are usually the sequelae of a fracture of the iliopectineal or ischiopectineal bone or separation of the pubes. One of two mechanisms may be responsible for such complications, namely a perforation of the

wall of the bladder by osseous spicules or a tear caused by violent traction exerted by the pubovesical ligaments. A combination of both mechanisms may take place in some cases causing multiple perforations at times.

Instead of a complete tear of the bladder wall, a partial rupture or so-called contusion of the bladder may occur. A unilateral or bilateral iliopectineal or ischiopectineal fracture a double or quadruple vertical fracture of Malgaigne's type, or a pubic or sacrospinous separation may cause brisk traction on the median aponeurosis of the perineum and a complete section of the urethra in a manner similar to the mechanism of a guillotine. Sometimes a fragment of a bone may pierce the urethra. The accompanying hemorrhage is caused by a tear of Santorini's venous plexus and the deep dorsal veins of the penis. The blood infiltrates the Retzius cavity and the ischioanal fossa and produces ecchymoses in the perineal zone.

A traction exerted by the pubovesical ligament and the median perineal aponeurosis may cause a simultaneous rupture of the bladder and the posterior urethra as was the case in 2 patients reported by the author.

The injection of air instead of a contrast medium for cystography may be advantageous for diagnostic purposes.

As to treatment, early exploratory laparotomy is indicated whenever a fracture or dislocation of the pelvis is accompanied by hematuria. The majority of authors, including the writer is opposed to Boehler's suggestion to treat intraperitoneal as well as extraperitoneal ruptures of the bladder by complete suture of the tear in the bladder and the skin without drainage. Supposedly the skin suture prevents infection of the extraperitoneal hematoma. The introduction of a retention catheter is the final step of the operation. Although in the author's opinion this procedure may be admissible in certain cases of intraperitoneal rupture which are treated early it is an undesirable method in extraperitoneal rupture of the bladder as it may have grave consequences. Suture of ecchymotic margins of the wound which may appear viable at operation may lead to post-operative disruption. Furthermore occlusion of the retention catheter by a blood coagulum may be followed by urinary infiltration of the soft tissues. The author advocates a cystostomy, the introduction of Pessier's catheter, and a local application of sulfonamides. A drain may be introduced into the Retzius cavity. The bladder is not attached to the abdominal wall.

Some writers advocate a reconstruction of the posterior urethra in case of rupture as soon after the accident as possible, while others recommend a cystostomy to be followed by a secondary reconstruction of the urethra after the fracture has healed. In selected cases the first method may be acceptable, but as a rule the second is preferable. If a rupture of the urethra is combined with a tear of the bladder a primary cystostomy is the method of choice.

JOSEPH K. NARAY, M.D.

Tabara, G., Lechner, C. and Hess, E.: Acute Interstitial Cystitis. *J. Urol.*, Balt. 1946 56 535

The authors report 3 cases of a new clinical entity which for want of a better name they have called acute interstitial cystitis. Each case presented approximately the same subjective syndrome namely marked urinary frequency, strangury and the passage of bloody urine.

The rograms in each case revealed a contracted bladder and overdistention of the ureters and pelvis of the kidneys. The picture resembled that seen in tuberculosis, malignancy and chronic interstitial cystitis. The condition is inflammatory and can be cured by large doses of penicillin and by arsenicals. The prognosis is good but recurrences have occurred.

FARMER, A. LLOYD, M.D.

Flocks, R. H.: Carcinoma of the Bladder. *Canad. M. Ass. J.* 1946 55 348

From 1930 to 1942 540 cases of carcinoma of the bladder (0.5 per cent of all cases and 5 per cent of all urological cases) were seen in the University Hospitals, Iowa City, Iowa. The majority of patients were in the age group between 50 and 80 years. Metastases were found in 41 per cent of the total number of cases. The most frequent presenting symptoms were hematuria and bladder irritation.

Tumors were classified into three main types: (1) papillary tumors, (2) infiltrating tumors confined within the bladder wall, and (3) infiltrating tumors extending through the bladder wall. Differentiation was made on the basis of the cystoscopic appearance of the tumor, the microscopic appearance of portions of it, and bimanual palpation under spinal or other anesthesia.

Of 168 patients whose tumors were considered papillary, 167 underwent transurethral resection. Eleven died of the operation. The disease was controlled in 130 patients. Twenty three died or are dying of their disease. Three could not be followed up. One patient who was fulgurated suprapubically died postoperatively of a urinary tract infection.

There were 149 patients with infiltrating tumor which was considered to be confined to the bladder wall. In this group 126 were treated by transurethral resection alone, with control of the disease in 67. Seventy-four were treated by transurethral resection combined with deep x-ray therapy with resulting control of the disease in only 23 cases. Forty-nine patients received treatment other than transurethral resection alone or combined with x-ray therapy. Five of 13 cases were controlled by partial cystectomy. One of 16 is known to be controlled by suprapubic fulguration. None of 6 cases receiving x-ray therapy alone was controlled. One patient underwent transurethral implantation of radon seeds without benefit. One underwent suprapubic implantation of radon seeds and is doing well. Two patients underwent total cystectomy and are doing well, however 3 patients died from complications of urinary diversion procedures preliminary to contemplated total cystectomy.

Transurethral resection was found to have definite palliative value in cases deemed incurable.

The author concludes that transurethral resection is an excellent method of treatment in approximately 50 per cent of cases of carcinoma of the bladder. Earlier diagnosis should increase the percentage of good results. This implies increased awareness on the part of physicians to the possible significance of hematuria and bladder irritation.

In cases not amenable to transurethral resection, i.e. all adenocarcinomas and all tumors with extensive infiltration, total cystectomy offers the greatest chance of cure, but its value is limited by the mortality associated with procedures necessary for urinary diversion. The author proposes a new method soon to be reported by which he believes the mortality can be lowered.

CLARENCE V. HODGETT, M.D.

Gorro, A. P.: Total Cystectomy (La cistectomia total). *Rev. esp. cir.*, 1946 3 197

In the author's opinion total cystectomy represents the only correct method of treatment of cancer of the urinary bladder. In this respect, cystectomy may be compared with gastrectomy, which procedure is not disputed by anybody as the method of choice for the treatment of gastric cancer. The final results of total cystectomy may be even better than those of gastrectomy because a cancer of the bladder can be diagnosed at an earlier stage. On the other hand, from the social point of view gastrectomy can be tolerated more easily than the mutilating removal of the urinary bladder which necessitates deviation of the urinary flow. Frequently total extirpation of the bladder is not selected by the surgeon because the lesion is circumscribed, but in reality the radical operation gives the best promise at that stage and carries a relatively small risk because of the good general condition of the patient.

There are four methods of diverting the urinary flow after total cystectomy: (1) transplantation of the ureters into the intestines, namely the colon or rectum; (2) implantation of the ureters into the hypogastrium; (3) implantation of the ureters separately into the iliac fossae; and (4) implantation of the ureters into the ilioiliac regions.

Attempts to create a new receptacle for urine out of an isolated loop of the intestines never became popular. The multiplicity of methods for deviation of the urinary flow proves that none is quite satisfactory and applicable in every instance. On the other hand there is a unanimity of opinion as to the operative procedures concerning the extirpation of the bladder: either the abdominal or the abdominopernical approach is used in accord with the local conditions.

As a rule implantation of the severed ureters into the skin is preferable to their implantation into the intestines. In many cases it is advisable to perform such an operation as the first stage of the entire procedure in order to improve the renal function and the general condition of the patient. The author does not approve of exploration of the lymph system in

the pelvis, lumbar region and along the aorta in order to extirpate the invaded ganglia, because when the condition is so far advanced extirpation of the bladder is no longer indicated. Symphysiotomy is contraindicated in view of the danger of infection of the bone. As a rule the author employs a low median incision. If the perineal approach is selected the author starts with the perineal incision and detaches the prostatic gland and the seminal vesicles from the rectum.

Every effort should be made to preserve the ureters which can be easily traumatized especially during the separation of the posteroinferior aspect of the bladder. If a considerable portion of the ureters is damaged great difficulties may be encountered in implanting them into the skin.

Trendelenburg's position is used for the operation. The vasa deferentia are ligated and the vascular pedicles are isolated and tied proximal to and in front of, the uterovaginal junction. In women an inverted V-shaped incision is carried through the anterior vaginal wall surrounding the external meatus of the urethra. The urethra can then be dissected up to the internal meatus. One or two rubber drains are inserted into the perineal wound in men. If the ureters are long enough both are implanted into the skin through a stab wound close to the midline. Each ureter is attached to the skin with four sutures placed through its muscular layer and adventitia. If the ureters are not long enough to reach the midline they are replanted in the iliac fossa in the vicinity of the anterior superior iliac spine.

Forty-eight hours after the operation the gauze sponges are removed from the hypogastric incision, while from the perineal wound they are extracted after 4 or 5 days. The rubber drains are withdrawn from the perineal wound 2 or 3 days later and are replaced by smaller ones. These drains prevent the formation of pelvic cellulitis which represents the most serious complication of the operation.

JOSEPH E. NARAY, M.D.

GENITAL ORGANS

Ferguson, J. D.: Carcinoma of the Prostate Treated with Estrogens. *Lancet*, Lond., 1946, 55.

Ferguson carried out repeated biopsies on 9 patients with carcinomatous prostates and accessible metastases in suitable cases during continued estrogen therapy and simultaneous estimations of acid phosphatase content of the affected tissues. All the patients had proved prostatic cancer and showed a good clinical response to estrogens. Ferguson used a Thompson resectoscope, and the tissue was removed from behind the posterior quadrant of the urethra above the verumontanum. The biopsy intervals varied from 10 days to 15 months.

The estrogen employed was stilbestrol or dienesol in doses of from 2 to 15 mgm. daily. In nearly all of the cases the neoplasm regressed from a glandular

adenocarcinomatous to a less cellular scirrhous form. In some cases a measurement of the nuclear diameter and computation of the tumor units were made and a definite decrease in number and size under therapy was revealed. The fresh biopsy material was stained for acid phosphatase and again the concentration of the enzyme diminished during treatment. There was no intimate connection between the concentration of acid phosphatase in the affected prostate and the amount in the blood serum. The serum value is undoubtedly derived from the quantity elaborated by the meta-tissues as well as by the primary growth.

Serial removal of several involved lymph nodes in 1 patient demonstrated regression of the metastases also. The author observed nipple tenderness, mammary swelling and pigmentation of the areolae, shrinkage of the testes, changes in complexion, and verruca in 66 per cent of the treated patients. The average survival period of 23 patients treated with estrogen was longer than that of 27 patients not so treated. About half of the deaths were due to delayed and often sudden reactivation of the tumor as though sensitivity to the estrogen was abruptly lost. In the present state of our knowledge it appears that estrogen treatment should be used early and continuously. DAVID ROSENBLUM, M.D.

McCrea, L. E.: Carcinoma of the Prostate; A Review of Treatment with Ethinyl Estradiol. *J. Clin. Biol.* 1946, 56: 697.

In its chemical structure ethinyl estradiol is closely related to algestradiol, the natural follicular hormone. It does not lose its potency upon oral administration. It is considered to be the most potent oral estrogen used up to the present time, being 6 times more potent than diethylstilbestrol.

The author makes an attempt to contrast the length of survival period, the disappearance of symptoms, and the end-results for a larger but untreated series, with a smaller but nonetheless typical series in which orchiectomy and estrogenic therapy were instituted.

In his series of 15 cases subjected to the combined therapy of orchiectomy and estrogenic therapy ethinyl estradiol was used instead of diethylstilbestrol. The dosage schedule routinely employed was a 30 day period in which 0.05 mgm. ethinyl estradiol was given once a day alternating with a 3 day rest period. One patient has been on such a regime for 27 months. The results attained were good, and more than favorably compared with the results attained with diethylstilbestrol, and warrant the further use of the drug.

An attempt was made to use the fall of the serum acid phosphatase level as an index of therapeutic efficiency but it was not uncommon to find the original level within normal limits. In these cases the diagnosis was made on clinical interpretations alone. It cannot be stated that a low primary level or a marked regression of the level should be a criterion in estimating the prognosis, extent of metastases, or severity of pain.

The author found regression of the prostate to be remarkable in most instances. In his series of 5 cases

not a single transurethral resection was necessary after the institution of combined therapy although many of the patients were in a state of acute urinary retention when first seen.

The side effects of ethinyl estradiol therapy were similar to, but less intense than those seen following the use of diethylstilbestrol. The use of vitamin B complex is suggested to relieve such side effects as exist. The breasts may become grossly enlarged and are sometimes painful, but this is less marked than with diethylstilbestrol. Edema of the lower extremities was slight in this series and in not a single instance did it become necessary to discontinue the drug.

The author concludes that the side effects of ethinyl estradiol are not as severe as those of diethylstilbestrol and that subjective improvement always followed its use.

JOSEPH E. MACKER, M.D.

Nixon, N. and Lewis, D. B. Mumps Orchitis. *J. Urol. Balt.* 1946 56 534

Epididymo-orchitis occurring in mumps, is responsible for long periods of hospitalization. Important to the patient is the possibility of atrophy of the involved testicle with subsequent sterility and impotence. Most authors report an incidence of testicular atrophy of between 40 and 60 per cent. Orchitis usually occurs before complete subsidence of mumps parotitis. In rare instances it may precede the parotitis by a number of days and in other cases it may be the only manifestation of mumps.

The temperature usually rises shortly before the patient begins to complain of testicular tenderness. A swelling occurs the fever rises sometimes to 103°F., and the patient complains of chilliness, back ache, malaise, nausea and vomiting. The testicle becomes hard, smooth, exquisitely tender and remains so for at least 4 or 5 days. The fever then drops by lysis and the swelling subsides the usual course of the orchitis taking about 10 days.

The invasion of the glandular tissue by the virus causes an edema of the former which is restrained by the firm, fibrous, tunica albuginea. In fulminating cases, hydrocele fluid accumulates between the tunica albuginea and the tunica vaginalis. This causes pressure necrosis of the seminiferous tubules with subsequent partial atrophy of the testis.

The shift in the blood picture from leucopenia and lymphocytosis to polymorphonuclear leucocytosis is further evidence of necrosis.

The medical treatment of orchitis is symptomatic. Convalescent serum, hot and cold applications and drugs are useless.

The author advocates the treatment of severe orchitis by surgical drainage. An incision 2 cm. long is made over the anterior surface of the scrotum under a per cent procaine infiltration anesthesia and the tunica vaginalis is incised. Usually the hydrocele fluid drains out under considerable pressure. A small Penrose tube is inserted beneath the tunica vaginalis and the wound is closed.

Of 339 soldiers with mumps at an Army Air Base 101 (nearly 30%) developed orchitis. In 68 of these

(67%) the orchitis was sufficient to warrant surgery. In 66 soldiers the above described technique was employed. In 2 the tunica albuginea was also incised by the technique of Wesselhoeft and Vose. Drainage was maintained for at least 24 hours.

Most patients showed almost immediate improvement with relief of pain, nausea, vomiting, and head ache within a few hours and reduction of the swelling within 24 hours. It was possible to follow up 27 of these patients. 26 revealed no evidence of testicular atrophy other than a slight degree of softening of the testicle in comparison with the firmness of its fellow.

FREDERICK A. LLOYD, M.D.

Baker, W. J. and Ragins, A. B.: Actinomycosis of the Testicle. *J. Urol. Balt.* 1946 56 547

A case of actinomycosis of the testicle in a 77 year old man is described as an incidental finding in a bilateral orchiectomy for the treatment of carcinoma of the prostate gland. The tunica vaginalis of the right testicle was loosely adherent to the tunica albuginea, and the testicle measured 5 by 3.5 by 3 cm. The surface made by cutting was brownish gray and studded by numerous abscesses which were filled with a greenish gray purulent material emitting a musty odor. The right epididymis showed no gross abnormal findings.

Since gross examination gave no clue as to the true nature of the condition the specimen was fixed before cultures were taken. The diagnosis of actinomycosis became obvious after microscopic studies. Because of the typical radiating fungus with bulbous mycelia at the periphery the organism may be considered as actinomyces bovis (Wolf Israeli type).

The condition is extremely rare. This represents the fourth case to be reported in the literature.

FREDERICK A. LLOYD, M.D.

Friedman, N. B., and Moore, R. A.: Tumors of the Testis; Report on 922 Cases. *J. Urol. Balt.* 1946 56 573

In a group of 922 cases of tumor of the testis occurring in males of military age who were serving in the Army of the United States the authors found that 96 per cent of these tumors could be classified into 4 fundamental structural patterns. These were seminoma (35%), embryonal carcinoma (10%), teratoma (7%) and teratocarcinoma (35%). Of the remaining 4 per cent, 1 per cent were interstitial cell tumors and the remainder fell into a miscellaneous category.

Seminomas showed mainly a homogeneous mononuclear pattern. They were composed of sharply defined, rounded polyhedral elements the cytoplasm was often clear. The nuclei clearly outlined were centrally placed as were the nucleoli. The nuclear chromatin was evenly dispersed. The cells were remarkably uniform and were usually arranged in an organized masses, separated by trabeculae of connective tissue. Occasionally the arrangements of cords and columns gave the impression of glandular structures but no lumens were formed. Micro-

scopically they appeared relatively benign, which appearance was consistent with the small incidence of regional and distant metastases and the low mortality rate.

Embryonal carcinomas, often confused with seminomas, differed not only in fundamental cell type but in biologic behavior and prognosis. The cells were frankly epithelial, often cuboidal or columnar and frequently formed differentiated glandular or papillary structures. Differentiation was often incomplete so that portions or all of the tumor consisted of unorganized solid epithelial sheets. The obviously anaplastic cells were larger than those of seminomas. The nuclei, which were large variable and bizarre, showed few traces of the orderly seminomatous pattern; the chromatin was clumped or regularly into large masses which stood out sharply against the clear background. Cellular types showed more variation from tumor to tumor than did seminomas. Significantly trophoblastic tendencies were seen in embryonal carcinomas.

Chorioepitheliomas have customarily been placed in a special category. However histological studies in this series indicated that the trophoblastic tendencies observed in embryonal carcinomas found full expression in the typical chorioepithelioma pattern, that of a combination of compactly grouped cytotrophoblastic cells and giant multinucleated syncytial structures. This, it was believed justified inclusion of chorioepitheliomas in the embryonal carcinoma group.

The somatic potentialities of testicular tumors were shown in the teratomas, which were characterized by the presence of epithelial masses, glands, and cysts, many of which were organized in combination with undifferentiated or specialized mesenchymal tissues, such as cartilage, into structural units. A teratoma is termed adult if it has no histologically recognizable malignant components

however metastasis of testicular tumors which appeared to be only adult teratomas is reported to have occurred.

The classification of teratocarcinoma was proposed for the large group of pleomorphic tumors in which both differentiated teratoid structures and histologically malignant elements were present. Rather than the conventional belief that the presence of embryonal carcinoma in teratocarcinomas is accounted for by malignant transformation of an adult structural component, the authors hold that the adult structures have differentiated in situ probably from the carcinomatous cells. This is supported by the intimate association of glands and other differentiated epithelial structures with both carcinomatous epithelium and organized mesenchymal components within the tumor.

A study of mortality rates and incidence of metastases indicated that for seminomas the immediate prognosis is good. In contrast the immediate prognosis is bad for embryonal carcinomas and chorioepitheliomas, and poor for teratomas and teratocarcinomas.

Ninety per cent of embryonal carcinomas metastasized as embryonal carcinomas or chorioepitheliomas. Roughly half of the teratoid neoplasms which metastasized gave rise to growths with teratocarcinomatous structures and half to pure embryonal carcinoma.

The authors state that the architecture of testicular tissue is not reproduced in seminomas and, therefore the term "seminoma" is inappropriate. They conclude that seminomas are probably tumors of primordial germ cells and should be called germiomas. Embryonal carcinomas and teratoid tumors, which are composed of evolving and differentiating somatic and trophoblastic tissues, are neoplastic expressions of the unlimited potencies of embryonic cells.

CLARENCE V. HODGES, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Schlumberger H G: Fibrous Dysplasia of Single Bones (Monostotic Fibrous Dysplasia) *Mil Surg.* 1946 99 504.

During the war the Army Institute of Pathology received tissue and records of 69 cases of fibrous dysplasia occurring in Army personnel. This paper reports the study of 67 of these which were monostotic. The ribs were most frequently involved and the small bones of the hands and feet were never involved.

The roentgenogram in this disease is not specific, and diagnosis is made by biopsy. The correct diagnosis was not made in any case by the roentgenologist. Eighteen resected ribs were studied.

The lesion appeared as asymmetrically fusiform or almost spherical swellings ranging up to 6 cm. in diameter. The surface consisted of thin but intact cortical bone. On section the cancellous bone and marrow were found to be replaced by a firm resilient yellow white tissue containing occasional small cysts which were usually filled with amber fluid. This tissue had a gritty character because of the presence of innumerable minute spicules of bone. Histologically the material resembled normal callus. Within the fibrous tissue, and most abundant at its periphery were trabeculae of partly calcified newly formed bone formed by direct metaplasia of the connective tissue.

The author believes that monostotic fibrous dysplasia can be distinguished histologically from neurofibromatosis by failure to find any nerve fibers in the lesion, but that ossifying fibromas and nonosteogenic fibromas are histologically indistinguishable from this disease and should be considered as variants of fibrous dysplasia. Albright's syndrome characterized by osteitis fibrosa disseminata, areas of pigmentation and endocrine dysfunction is a polyostotic fibrous dysplasia and probably has nothing in common with monostotic fibrous dysplasia. It is not a congenital anomaly.

Evidence is presented to suggest that the disease may represent a disturbance of the normal reparative processes following injury to bone.

VERNON C. TURNER, M.D.

Newman, F W: Paget's Disease. A Statistical Study of 83 Cases. *J Bone Surg.* 1946 28 798.

This study covers a 15 year period at the Hospital of the University of Pennsylvania representing an incidence of Paget's disease of over 0.06 per cent of the total of about 127,000 case histories.

The disease was fairly equally distributed between males and females, over 40 years of age in 79 cases among which 70 patients were over 50 years of age. Only 3 cases occurred in individuals under 40 years

of age. In only 48 per cent of the cases were the chief complaints closely related to Paget's disease. In the remainder the Paget's disease was an incidental finding.

The bones involved were chiefly the pelvis, skull, spine, and femur but there were some cases in which the tibia, humerus, radius, fibula and metacarpals were involved.

The calcium (blood serum) varied from 9.4 to 12.2 mgm. per 100 c.c. The serum phosphorus levels ranged from 2.6 to 6.75 mgm. per 100 c.c. The alkaline phosphatase level showed a definite elevation in most cases and is considered by the authors as the most useful of all laboratory procedures. The serum phosphatase levels varied from a low normal of 0.8 Bodansky units to a high of 175 units. The acid phosphatase levels varied from a normal low of 0.1 to 2.0 units. The alkaline-phosphatase levels varied from a low normal of 2.6 to 48.8 units.

The roentgenograms were diagnostic, the differential diagnosis from metastatic carcinoma from the prostate being very important. The complications in the order of their frequency were cranial nerve pressure, fractures, urinary calculi and sarcomatous degeneration. In this series there were only 2 proved cases of sarcoma.

Relief of the presenting symptoms was directed by the respective specialties. Roentgenotherapy was formerly given in an attempt to relieve pain. Magnesium carbonate powder 1 teaspoonful 2 or 3 times daily and a low calcium diet were recommended.

DANIEL H. LEVINTHAL, M.D.

Herdner and Malgras: Costotransverse Tuberculosis Osteoarthritis (Osteo-arthritis tuberculeuse costo-transversaires) *Rev. orthop., Par.* 1946 32 331.

The authors believe that they have identified a localization of tuberculous osteoarthritis that has never before been described. A few cases of tuberculous osteitis of the transverse processes have been described but this was an osteoarthritis that involved the rib, the transverse process, and the joint which connects them. Two cases are described in women 48 and 37 years of age who for months had suffered agonizing pain. Tuberculosis of this very small joint is more serious than that of larger joints like the knee because relief cannot be procured by immobilization. The slightest movement even that of respiration or coughing causes the most intense pain. In both of these cases when the lesion had been localized operation was performed and the patients were completely relieved.

The point that is most emphasized in the article is the necessity for tomographic examination in these cases. A simple roentgen examination is only the first step in the diagnosis. It must be completed by an extremely careful tomographic examination of the

region in which the lesion is suspected this reveals the lesion by taking away with the shadows of neighboring organs.

The tomograms of these cases are reproduced and a detailed discussion is given of the manner in which the lesions were revealed. Diagrammatic sketches of the involved regions are shown.

AUDREY G. MORGAN M.D.

Hamilton J. B., Barner J. L., Kennedy P. C., and McCort, J. J.: The Osseous Manifestations of Eosinophilic Granuloma. Report of 9 Cases. *Radiology* 94:6 47-445.

Case studies of 9 patients with eosinophilic granuloma of bone are presented. All of the patients were seen in an Army General Hospital and were young males. The laboratory findings were normal except as follows: in 2 cases the alkaline phosphatase was increased to 7 and 7.9 Bodansky units, respectively; the sedimentation rate was increased significantly in 1 case; a sternal marrow puncture was made in 1 case and the smear was normal.

Röntgenologically all lesions tended to be osteolytic. In the skull the lesion had little respect for suture lines and usually involved both tables.

The differential diagnosis included the following: fibrosing osteitis developing after a closed injury to the skull; meningiomas (however these usually show more erosion of the inner than of the outer table); epidermoid cysts (which originate in the diploe and expand through both the inner and outer tables); solitary bone cysts; multiple myeloma; osteitis fibrosa cystica; and low grade osteomyelitis.

There is a long discussion of the relationship of this disease to Hand-Schüller-Christian's disease or lipogranulomatosis, and to Letterer-Siwe's disease also called reticulosis or neoplasmic histiocytosis.

In this series, with a relatively short period of follow-up there was no roentgen evidence that roentgen therapy altered the course of the disease, although it did appear to relieve pain.

VERNON C. TURNER, M.D.

Peša, K.: Changes in the Bones of the Wrist in Workers with Pneumatic Tools (Směny na kostru zápěstí při práci pneumatickým nářadím). *Laborský listy* 94:6, 249.

The tools included in the workman's compensation law are the pneumatic drill, pneumatic riveter and the pneumatic hammer. They do not include the tools fixed to an immobile base. The intensity of the percussive effect depends upon the weight of the tool (from 7 to 35 kgm.) the rapidity of the strokes (from 250 to 4,000 percussions per minute) and the length of the stroke (from 12 to 350 mm.). The more tightly the instrument is gripped the less is the impact.

The bones most commonly affected are those of the wrist, although the literature also reports effects in the acromioclavicular shoulder and elbow joints, and even spondylitic changes in the spine. The last effects are ascribed to using tools while in the hori-

zontal decubitus which, even if it does not induce the vertebral changes could certainly aggravate a spondylosis already present. In addition, there are also described vague effects on the joints, muscles, blood vessels, and nerves. The law recognizes that the progressive effects should require constant exposure to the percussive effects for a sufficient length of time (at least 2 years).

The author reports 7 cases for the Brno region in Moravia during the years from 1939 to 1943. In 5 cases the shoulder joint was the part involved in 1 the elbow joint, and in 1 instance there was an extensive atrophy of the muscles in the region supplied by the cervical plexus (pectoralis major, supraspinatus and trapezius muscles).

The remaining 3 cases were wrist injuries. In 1 of these there were no roentgenological findings and the author a roentgenologist does not attempt to discuss it. The other 2 cases, including the roentgenograms are reported in detail. In 1 patient extension at the wrist was practically nil and the other motions were markedly diminished. The roentgenogram for the year 1939 disclosed a lunate flattened to half of its normal height with a pathological fracture. In the substance of the bone were cystic areas alternating with areas of condensation. In the other bones of the wrist there was a longitudinal arrangement of the bone prominences and in these bones, as in the ulnar styloid process, cystic changes were visible. In most of the wrist joint surfaces arthritic changes were visible. Six years later the bones were largely reconstituted however the deformities and other arthritic manifestations were unchanged.

The remaining patient presented much the same history, development, roentgen findings, and residual loss of motion in the wrist joint, except that the left wrist was the joint involved. There was an early history of injury to the joint, and 4 years later the cystic changes had not entirely disappeared.

JOHN W. BREDEN M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Marino, H.: Volkmann's Contracture of the Upper Extremity. Technique of the Explorative Operation (Contractura braquial de Volkman de miembro superior. Técnica de la operación exploratoria). *Boi Acad. argent. tr.* 1944, 23, 0.

The need of surgery in the treatment of Volkman's contracture at the moment of its appearance in order to avoid further development, as well as after it is once established, has been emphasized by Bardenheuer, Leriche, Tavernier, and among Argentine surgeons, by Ceballos, Gioia, and Fitte. However none of these authors has described a satisfactory technique which will facilitate the approach to the somewhat complex region in an urgent case, and save as many nerves, vessels, and muscles as possible.

Because of the ischemic paralysis of the upper limb resulting from fractures or vascular lesions, the operative procedure must ensure a perfect approach to

Fig. 1. a, Incision line. b, Aponeurotic layer. c, The incision of the aponeurosis shows the nerves, vessels, and the pronator teres. d, The artery and its branches, and the median nerve covered by loose connective tissue and easy to reach. This is the site where compression lesions begin

e, The dissection of the pronator teres is followed downward showing the flexor digitorum sublimis and the artery and nerve lying underneath. f, The investigation of the ulnar nerve.

the lower part of the arm and anterior part of the elbow and forearm with good vision of the median and ulnar nerves the brachial artery and its branches, and the radial and ulnar arteries. Incisions have to be wide and easily extendible. Fiolle and Delmas devised a technique which was applied to elbow injuries in World War I this allowed the exploration of the three main arteries of the upper limb although it did not permit the study of the ulnar nerve and the lower portion of the forearm.

The author proposes the following technique: the incision starts at the inner edge of the biceps at the juncture of the middle and lower third of the arm, following that edge downward crossing in front of the elbow bending toward the axis of the limb and following that line as far as necessary.

In early cases the surgeon will find branches of the medial brachio-cutaneous nerve in the subcutaneous tissue and the musculocutaneous nerve below them. Sometimes the superficial vessels have to be cut, but in older cases they will not exist or will be very small. Dissection must be performed even if it is difficult because of infiltration of the tissues.

The first element to be studied is the median nerve which can be seen at the internal edge of the biceps muscle and under the brachial aponeurosis. It is freed with the scalpel and section of the aponeurosis is continued downward following the incision line (b). This incision of the forearm is performed between the pronator teres and supinator longus in the form of a channel in which the nerve lies (c).

Section of the aponeurosis is important in early cases, because it constricts the vessels and nerves after fracture or the development of a hematoma. One can see how the circulation improves after section.

The investigation of the brachial artery is easy: it is found in the arm just lateral to the median nerve

and surrounded by veins. If the artery is of good size, it should be followed upward to a normal area where a periarterial sympathectomy is performed. If the caliber of the artery is very small or the artery does not exist an arterectomy is advised with two ligatures including the injured portion.

The nerve is often only partially injured and a good dissection will permit wrapping it with muscular tissue. If the continuity is lacking it must be re-established by a graft at a second operation.

In this manner the vessels and nerves of the arm elbow and upper part of the forearm are liberated. However sometimes the lesion is in the lower third of the forearm, in which case the investigation must be continued downward. The section of the pronator teres frees the nerve lying under it. The artery must be traced also for it may be that the artery and nerve are pressed under the flexor superficialis at the radial and ulnar insertions, and its section will release them (e).

The ulnar nerve is not always injured as it is better protected than the median. It can be seen through the superficial aponeurosis at the inner edge of the forearm. It is easy to recognize because of its size (f) and if it is followed upward it will be seen that it divides the insertions of the flexor carpi ulnaris. If desired the investigation can be continued upward through the supracondylar groove.

Once the section of aponeurosis and scars is complete and the treatment of nerves and arteries accomplished the wound is sutured that is, only the subcutaneous tissue and the skin. The aponeurosis and injured muscular fibers are left loose to avoid recurrence. Immobilization with a plaster splint is advised during the healing period. Afterward mobilization physical therapy and thermotherapy will complete the treatment aiding the return at least partially of the movements of the limb.

H MARINO M D

Guilleminet M., Roy J. C. and Andrie G.: Results of Arthroplasty of the Finger Joints (Résultats de l'arthroplastie des articulations digitales) *Rev orthop* Par 1946, 3 277

Little is known of the late effects of arthroplasty of the finger joints. The authors therefore describe and illustrate with photographs 5 cases in which they have operated, the most recent one 6 months ago and the oldest 9 years ago. The results were very good in 3 cases and poor in 2 cases.

The authors overcome the ankylosis by removing the sclerotic periarthritic tissue restoring the joint surfaces as nearly as possible to their original form and placing between the two surfaces some substance which will prevent osteogenesis and renewed ankylosis. They have used fascia lata in all their cases. The operation is performed best under general anesthesia and the incision may be lateral or dorsal. This operation is indicated in post-traumatic ankylosis but not in ankylosis following infectious arthritis, and probably not in those due to chronic rheumatism although the authors have had no experience in this form.

A good part of the effect of the operation depends on the patience and skill of the patient in re-educating his fingers. This is a long and painful process and some patients will not keep up the necessary tedious daily exercises after they are dismissed from the physician's care. The best result was obtained in the case of a physician who needed his finger for gynecological and obstetrical examinations and who exercised great patience and skill in the re-educating exercises. On the other hand one of the patients who could not be kept under observation was evidently careless in this respect and the result obtained in this case was not very satisfactory.

UDRAY G. MORRAN, M.D.

Schwartz, R. P.: Arthrodesis of the Subtalar and Midtarsal Joints of the Foot. *Surgery* 1946 30 69.

Impairment in the function of locomotion may be due to deformity with or without instability of the foot resulting from trauma, infection, disordered nerve impulses or congenital influences. A fairly comprehensive historical review is presented describing the various methods of stabilization.

The author describes his preoperative analysis to reveal the individual variations and carefully plan the correction of the particular structural abnormalities. Mediolateral and plantar dorsal roentgenographic tracings are made preoperatively and the lateral view is cut into three parts: the upper representing an outline of the astragalus and lower tibia; the inferior posterior representing the calcaneus, and the inferior anterior representing the foot anterior to the metatarsal joint. These sectional tracings are superimposed upon each other; the composite representing the optimum restoration desired and the amount of cartilage and bone which must be removed. This restoration is checked with the lateral view postoperatively.

DANIEL H. LEVINTHAL, M.D.

Tavernier L.: Pseudarthroses with Bone Loss Treated with Flexible Bone Grafts and Intra-medullary Wire (Pseudarthroses avec perte de substance osseuse traitées par greffes spongieuses sur broche métallique intra-médullaire) *Lyon chir* 1946 41 345

The treatment of pseudarthroses with bone defect always has been a difficult problem. A rigid bone graft can be readily employed in cases in which large bones are involved. Even then the condition often is complicated by secondary fracture of the bone graft. In pseudarthroses of slender bones, such as the bones of the forearm, fixation of rigid grafts is extremely difficult and disalignment of the fragments very often occurs. The use of flexible grafts (osteoperiosteal or cancellous bone) facilitates the procedure considerably but it is difficult, if not impossible, to keep the fragments in proper alignment. Immobilization in a plaster cast is often sufficient, but it is inadequate in many cases, for example in pseudarthroses of both bones of the forearm.

The method of using flexible grafts and intra-medullary wires has the advantages of both methods without their faults. Maintenance of the position of the fragments is as secure as with the use of rigid grafts, the procedure is simple, and the osteoperiosteal graft has the same osteogenic qualities as the cancellous bone grafts.

The advantages of this method are clearly demonstrated in pseudarthroses of both bones of the forearm. The 4 fragments are brought into proper alignment with Kirschner wires. The fixation is sufficiently mobile to allow the application of flexible bone grafts without losing reduction. A plaster cast is used for additional immobilization of the forearm in midposition. The ultimate result of this type of treatment was much better than that ever obtained by rigid fixation.

This procedure was used in 8 cases, 2 of which were pseudarthroses of both bones of the forearm. Preliminary to the bone grafting scars are excised and the adjacent joints, muscles, and tendons are limbered up with the help of physical therapy. The incision is carried along muscle layers or already existing depressions caused by scar tissue adherence to bone. The bone is freed proximally and distally to the fracture line for a distance of about 3 or 4 cm. There is a tendency to save no exposure to preserve the blood supply to the area, but this makes the operation much more difficult and eventually one is compelled to extend the incision to establish good contact of the host bone with the bone graft. Scar tissue is excised until normal muscle is encountered. This is done to assure proper blood supply. The medullary cavity of both fragments is opened; these cavities are usually closed by a plug of condensed bone. Then the Kirschner wire is inserted into the medullary cavity of both fragments. In case of pseudarthroses of the ulna the wire is inserted through the olecranon and in case of the humerus, through the head in the region of the shoulder. In case none of the portions of the bone is easily accessible like in

the radius an opening is made in one end of the bone extending obliquely into the medullary cavity. The Kirschner wire is made to follow the opening and is guided into the medullary cavity across the pseudarthrosis site into the other fragment. The wire is then cut even with the bone surface. In wiring the radius the opening is made on the dorsal aspect of the distal end of the bone. The osteoperiosteal grafts are removed from the anteromedial aspect of the tibia long enough to cover the defect in the host bone and to extend 3 to 4 cm on each fragment. These grafts are placed with their rough sides toward the host bone and are fixed by encircling catgut sutures. The muscular and fascial layers are closed snugly to hold the grafts in place.

Although cancellous bone replaces bone defects faster and unites more readily with the host bone the author prefers the osteoperiosteal grafts because of the added stability. The skin is closed. A cast is applied. Roentgenograms are taken after a month.

Three cases are presented: a pseudarthrosis of the radius of the humerus and congenital pseudarthrosis of the tibia.

A soldier 25 years of age sustained a double fracture of the radius due to a shell explosion in February 1944. In February 1945 he was operated upon in a military hospital because of a persistent pseudarthrosis. In November 1945 malunion of the proximal fracture site was apparent. The pseudarthrosis of the distal fracture persisted. The bone graft used for the repair of the distal fracture at the first operation was found to be dead and had to be excised in the second attempt at repair. At the second operation the malunion of the proximal fracture was osteotomized and the fibrous tissue forming the pseudarthrosis of the distal fracture was excised. The marrow cavity was opened in all three fragments. Through a prepared opening in the distal portion of the radius a Kirschner wire was inserted and guided proximally into the medullary canal through all three fragments. The alignment at the proximal fracture site was satisfactory but there remained a defect from 2 to 3 cm. in length at the distal fracture site. A long osteoperiosteal graft taken from the tibia was placed over the radius to extend from 3 to 4 cm. distally and proximally beyond the fracture line. The graft was fixed with catgut to the upper and lower fragments.

At the end of a month there was still some motion at the distal fracture site and a new cast was applied. At the end of 2 months the consolidation was complete but there was considerable dorsal deviation of the distal end of the radius. An osteotomy corrected the deformity of the radius. At the end of another month consolidation of the fracture sites was complete. The shape of the forearm supination and pronation were nearly normal.

Without the medullary splinting with Kirschner wire repair of the malunion would have failed and the result most likely would have been a "Z" shaped deformity of the radius which would have blocked pronation and supination.

The author reports the case of a 19 year old female who had had acute arthritis of the left hip and right shoulder when a child. Several years before the left hip had been reconstructed by an arthroplasty. Osteomyelitis of the right humerus caused growth arrest in that bone. The humerus measured only 17 cm in the roentgenogram. The patient requested that the arm be made longer because she wanted to get married. On December 12 1945 a "Z" osteotomy was done on the midportion of the humerus. A Kirschner wire was inserted transversely into each end of the bone and traction of 5 kgm. was applied to each end. It is generally difficult to get more than 4 cm lengthening in a normal extremity. After a few days of traction a gain of 10 cm in length was observed. The traction was removed and a weight was attached to the wire through the distal end of the humerus the patient being allowed to be ambulatory and carry the arm in a sling. Bony union at the osteotomy site did not take place. On February 18 1946 a bone grafting operation was done. Two osteoperiosteal grafts were used the longer graft was placed on the anterior aspect of the humerus and the shorter one was placed on the posterior aspect of the bone. The grafts were held in place with catgut sutures. Prior to this procedure a Kirschner wire was inserted into the medullary canal to bridge the bone defect.

On the tenth postoperative day a superficial abscess had to be incised. In spite of a persistent fistula bony union was observed on the seventieth postoperative day. The arm was from 6 to 7 cm longer.

In another case a child was admitted to the hospital in January 1943 because of a deformed leg. There was considerable bowing of the lower leg in its distal third. This deformity followed a fall 2 months prior to admission. On March 5 1943 a sliding bone graft was applied by following Albee's technique to correct the deformity. Because of an "osteolytic process" the graft as well as portions of the proximal and distal fragments became resorbed. In spite of walking casts and caliper braces the outward bowing of the leg increased more and more and finally the fibula broke. It was generally agreed that this was not a simple fracture of the tibia caused by a fall but a congenital pseudarthrosis of the tibia. Further questioning of the parents confirmed the diagnosis. On February 15 1945 an open reduction with bone grafting was done. The scar tissue between the fragments was excised. By means of a manual osteotomy of the fibula satisfactory alignment of the bones of the leg was made possible. A Kirschner wire was inserted into the medulla of both fragments of the tibia and cut even with the cortical surface of the bone. An osteoperiosteal graft was taken from the other tibia and fixed to the host bone with encircling catgut sutures. Smaller bone grafts were used to fill the defect between the bone fragments.

The plaster was changed one month after operation. One hundred days after the operation the pa-

tient was allowed to be about in a 'Delbet plaster'. Re-examination after another month, however revealed motion at the fracture site and some decalcification of the distal end of the graft was noticed. On July 23, 1945 another operation was done. Fibrous and fibrocartilaginous tissue was found to bridge the defect. After excision of the fibrous tissue an osteoperiosteal graft taken from the other tibia was used to bridge the bone defect. At the end of a month union was almost complete and walking in a 'Delbet plaster' was allowed. A roentgenogram taken in March, 1946 revealed that the Kirschner wire broke at the level of the old site of the pseudarthrosis. The wire was extracted. Today the patient walks without any difficulty although the leg is about 3 cm. shorter.

In conclusion it is pointed out that the outlined procedure is very effective in cases in which union usually is very difficult to obtain. Infection usually destroys the graft and interferes with the formation of solid callus yet it failed to prevent the formation of callus and to destroy the graft in the cases treated by the author. Another interesting observation was the fact that the Kirschner wire broke even after union was established. The author was forced to extract a Kirschner wire which was left in a tibia with pseudarthrosis for several months. This wire was made of steel covered with chrome (not of nonoxidable steel). He observed that the wire was superficially oxidized along its entire length. The portion of the wire which came to lie at the level of the pseudarthrosis was eroded and three quarters of its thickness was destroyed. Evidently the wire did not break because of some mechanical factor since the fracture appeared to be healed at the time when the wire was already broken. It broke because of the "biological processes of oxidation" that take place at the site of a healing pseudarthrosis. This also explains the fact that the intramedullary grafts used in the repair of recent fractures and pseudarthroses frequently break transversely at the fracture site. It is apparently due to the action of "very active oxydases" which are found in areas where bone is rebuilt.

Similar favorable results were obtained in the 5 other cases treated in a similar manner and the author feels justified in stating that this type of treatment is easy and efficient.

GILBERT I. RYAN, M.D.

Adams, A. O.: Neurectomy to Produce Atrophy of the Amputation Stump. *J Bone Surg.* 1946 8 76.

The author believes that neurectomy offers the advantage of causing a more rapid and complete atrophy of the amputation stump in large muscled adults rather than other operative procedures. The object is to produce a conically shaped stump. This was achieved in 5 cases in 3 of which the nerve operation was done at the time of primary amputation. In the 2 other cases, subsequent nerve operations were performed.

A longitudinal incision $3\frac{1}{2}$ inches in length is made in the lower part of the popliteal space, extending down the leg. The medial sural cutaneous nerve should not be damaged. This nerve may be used as a guide to follow down into the popliteal space to the tibial nerve. The muscular branches of the tibial nerve to the two heads of the gastrocnemius are identified and completely sectioned. The branch to the soleus leaves the tibial nerve at a lower level, but is within the operative field and may be sectioned. The location of this incision is such that the scar has not been objectionable. C. FRED GORDONSON, M.D.

FRACTURES AND DISLOCATIONS

Urist, M. R.: Complete Dislocations of the Acromioclavicular Joint. The Nature of the Traumatic Lesion and Effective Methods of Treatment with an Analysis of 41 Cases. *J Bone S.* 1946, 18 83.

An analysis is presented of 41 cases in which there was a complete dislocation of the acromioclavicular joint. All of the patients were strong active young soldiers who variously acquired their injuries through acts of violence. Twenty-three of these injuries were acute and were recognized early; the remaining 18 cases were chronic. Eleven cases reported in both groups presented associated fractures of the clavicle, the acromion process, and the coracoid process.

A table is included showing a classification of anatomical variations in the acromioclavicular joint in 100 random roentgenograms of the shoulder. The mechanism of injury and the traumatic lesion are discussed. Experimental observations are reported. An examination of resected joints is reported. The following were of value during treatment: (a) widening of the joint spaces; (b) ballooning; and (c) evolution of the symptoms. Another table contains significant data regarding 18 complete dislocations of the acromioclavicular joint treated by early reduction and immobilization for 6 weeks. In 12 cases the results were excellent and in 6 there were residual symptoms. A similar table shows significant data regarding 11 complete dislocations of the acromioclavicular joint seen late and not treated. All of the patients had marked residual symptoms. Another table presents significant data regarding 5 complete dislocations of the acromioclavicular joint treated primarily by various methods. In 3 there were excellent cosmetic results with pain while in 2 there was slight deformity and subluxation with no residual symptoms. The purpose of treatment in these cases is to secure anatomical reposition and to relieve the symptoms. On the other hand, a patient with a poor anatomical result may have no symptoms. Conservative methods of reduction of the dislocation include bandages, adhesive dressing and strapping, suspensions, harnesses and braces, and plaster of Paris splints.

Fifteen shoulders with complete dislocation of the acromioclavicular joint were treated by means of a plaster jacket applied around the body to the level

of the axillae. A pad was placed across the dislocated acromioclavicular joint and an elastic shoulder strap was stretched tightly over the clavicle. Then the ends were doubled back on themselves between layers of plaster bandage incorporated in the body cast to maintain constant pressure. The scapula was elevated by means of raising the shoulder girdle and incorporating the upper extremity to the body cast in this elevated position. Immobilization was continued for 6 weeks. Twelve of the 15 soldiers returning to duty were completely cured after a period of physical therapy and rehabilitation. In 1 case subluxation developed without pain or limitation of motion. The 2 remaining cases presented subluxation associated with symptoms eventually the patients were subjected to surgical treatment.

The surgical methods used were open reduction and internal fixation arthrodesis coracoclavicular screw fixation skeletal traction and excision of the outer end of the clavicle. Primary excision of the joint is probably not justified in dislocations associated with fractures until a period of duty establishes disability. Complications and sequelae are discussed. The chief obstacle to effective conservative treatment has been found to be interposition of parts between the joint surfaces. Excision of the outer end of the clavicle was used successfully in 9 cases in this series.

RICHARD J. BENNETT JR., M.D.

Kestler O. G.: Recurrent Dislocation of the First Carpometacarpal Joint Repaired by Functional Tenodesis. *J. Bone Surg.* 1946 28 858

A review of the literature disclosed that 3 procedures have been suggested for the radical cure of recurrent dislocation of the first carpometacarpal joint. A case report is presented. The operation devised takes into account that the tendons have a logical anatomical course and that the function of the muscle should actively hold the involved bone in place. Also the procedure should not interfere with the original function of the tendon. The author states that these requirements were fulfilled in the case reported. The operative procedure which uses the abductor pollicis longus tendon is explained in detail.

RICHARD J. BENNETT JR., M.D.

Cobey M. C. and White R. K.: An Operation for Nonunion of Fractures of the Carpal Navicular. *J. Bone Surg.* 1946 28 757

Operative procedures are not considered in fractures of the carpal navicular until a full trial of immobilization has been given. Twelve weeks is considered a reasonable period for union. No fracture older than a year was grafted in this series. The criteria of nonunion are based on roentgenographic findings alone. The operative procedure is explained in detail. The bone graft can be removed from the distal quarter of the radius. Three drill holes are carried across the line of fracture from one fragment into the other. Three square peg grafts $\frac{3}{4}$ inch in diameter are made and driven into the individual holes made by the drill. A cast similar to that used

for fracture is applied. A roentgenogram is taken at the end of 6 weeks. After union is complete active motion in graduated exercises is started.

Ninety cases have been treated. Of these, 51 were fresh fractures. The average time required for union in these fresh cases was 7.4 weeks. There were 2 cases of nonunion. Both union subsequently reformed in these 2 cases after bone grafting. Thirty-nine old cases of nonunion which had been treated previously were seen; these ranged from 5 months to 18 years in duration. Two of these were suitable for the bone graft operation. Of the 10 cases among the untreated fractures in which there was nonunion 7 resulted in union. The average period of immobilization after operation was 9.6 weeks. The history of 6 cases is reported in detail.

RICHARD J. BENNETT JR., M.D.

ORTHOPEDICS IN GENERAL

Hollinshead, E. H., and Markee, J. E.: The Multiple Innervation of Limb Muscles in Man. *J. Bone Surg.* 1946 28 721

By a careful and rather complete dissection of one cadaver supplemented by the use of routine dissecting laboratory material the authors show that of 58 long muscles of the limbs with separate heads of more than one point. Ten of these 15 were known to receive more than one branch in other individuals. These multiple branches may enter the muscle close together or may be distributed for some distance over the length of the muscle. In neither pattern of branching can the ultimate distribution of the nerve fibers within the muscle be deduced from a purely morphological study. Other authors have shown that the multiple nerve branches entering a muscle may control contraction of different segments along the muscle.

DANIEL H. LEVINTHAL, M.D.

Sweetapple, H. A.: Sudeck's Atrophy. *Med. J. Australia*, 1946 2 581

A typical case of Sudeck's atrophy is one which sustains a relatively minor injury to a limb accompanied by an intractable pitting edema stiffness of the musculotendinous apparatus and roentgenological evidence of bone decalcification. Moreover immobilization in plaster Paris rest and other forms of empirical treatment retard progress rather than ameliorate the syndrome.

The disorder is based upon a vasomotor dysfunction. The skin is dusky red and it may be hot or extremely cold. Pain swelling and osteoporosis are thought to be secondary to vasomotor changes in the deeper structures of the limb. When these manifestations prevail for a long period the basic disorder spills over into the autonomic nervous system and the morbid alteration of the affected parts are too long reversible.

It is the author's contention that Sudeck's atrophy is a misnomer. Early in its incipency the syndrome reveals a mottled appearance of the bone later a

uniform osteoporosis ensues. Diagnosis of the disease should be made prior to the appearance of generalized osteoporosis, rebellious edema and the intractable pain. Macroscopically the effects of Sudeck's atrophy on the bone architecture may show loss of cortical definition, fading of the lamellae, considerable thinning of the cortex, rendering it roentgenologically indistinguishable from tuberculous osteitis.

Etiology. Hyperemia and sympathetic reflex irritability are mentioned. Equivocally enough, sympathectomy cures the syndrome on the ground of complete peripheral vasodilatation. That calcification is due to hyperemia and vice versa is maintained by Leriche and others. However after a perusal of the various hypotheses connoted in the article one cannot conclude that the mechanism of Sudeck's atrophy is fully understood.

Treatment. 1. Sudeck's atrophy is said not to exist if the patient responds to rest, immobilization and manipulation. In such cases the diagnosis is erroneous. 2. If a vicious circle exists because of thrombosed vein, adhesions of local nerve, and adjacent structures, correction of each of these abnormalities proves effective. Blocking of a trigger point with novocain, stripping of the adventitia of the main artery of the limb, as advocated by Leriche and his co-workers, or amputation and alcohol or novocain sympathetic block is beneficial in a substantial number of intractable cases.

The author discusses three typical cases in which periarterial stripping was followed by a dramatic relief of pain, cyanosis, and osteoporosis.

SAMUEL L. GOVERNALL, M.D.

Gilman, D. J.: Hallux Valgus and Hallux Rigidus. *Med. J. Australia*, 1946, 385.

Hallux valgus, the most common deformity of the foot, per se is accompanied by other foot disorders. Flat foot and contracture of the toes are concomitant

deformities. Similarly the symptoms manifested are not necessarily those of hallux valgus. On the contrary the symptoms are due to a general defect in the function and structure of the foot in which all of the toes sooner or later are involved. The deformity may be unilateral or bilateral. In the majority of instances, the deformity is not a primary one, but it may be a congenital anomaly of the first metatarsophalangeal joint. Moreover the writer emphasizes that painful feet in children whose parents already have hallux valgus may be harboring the deformity as early as the tenth or twelfth years of age.

The lengthy technique can be justifiably summarized as follows:

An elliptical skin incision is made. The extensor tendons are reflected and possibly lengthened. The periosteum of the first metatarsal bone is stripped and a wedged osteotomy is performed just proximal to the reflection of the attached metatarsophalangeal capsule. The two bones are completely osteotomized and the medial cortical spike is abutted laterally to the distal base or head of the metatarsal bone. The periosteum, fascia, and skin are then closed. Immobilization in the overcorrected position is accomplished with an aluminum splint insulated with plaster of Paris.

The etiology of hallux rigidus includes trauma, infection, osteochondritis juvenilis, and Scheuermann's lesion. The symptoms of hallux rigidus may be those of pain, impaired range of motion of the big toe, marginal osteophytes and in severe cases flexion deformity of a crippling nature.

Treatment is not to be instituted in children until they have passed the age of 12. In older patients, in whom fusion is the treatment of choice, the author encountered failures particularly when the articular surfaces were hard eburnated or sclerosed. In the majority of cases, however, fusion was both satisfactory and worthy of continued application.

SAMUEL L. GOVEY, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Kimbarovskii, M. A.: Experiences with the Operative Treatment of Aneurysm and of Pulsating Hematoma from 1941 to 1946. *1 rubezhno Delo* 1946, No 66 338

Of the 237 cases forming the basis of this report 8 were involvements of the common carotid artery, 3 of the external carotid artery, 1 of the internal carotid artery, 2 of the transversa colli artery, 1 of the transversa scapulae artery, 1 of the vertebral artery, and 1 involving 3 arteries of the neck (vertebral, internal carotid, and a smaller artery). There were 18 cases involving the subclavian artery and 1 case involving the long thoracic artery. There were 51 arterial involvements of the upper extremities and 140 of the lower. Of these, those of the femoral artery showed a preponderance with 76 cases. However, since the arteries of the extremities did not offer anything unusual in diagnosis, surgical treatment or results obtained, they are not given special discussion. The injury to the blood vessel resulted from a bullet in 122 (51.5%) of these patients, from splinters of shell and airplane bombs in 22 (9.2%), and from mines in 93 (39.3%). This shows a paucity of bullet wounds in comparison with previous wars. The formation of the aneurysmal sac may not occur until weeks or even years after the injury to the blood vessel, and its appearance may be wholly unexpected. In 1 of the author's cases the diagnosis of phlegmon was made by the consulting staff of the hospital.

There are surgeons who do not believe in immediate operation, in the hope of obtaining spontaneous healing; however, this occurred in the author's material in only a single instance. In general, he believes that the arterial aneurysm, while still small and not endangering the blood supply to the extremity, justifies a waiting attitude in individual instances. On the other hand, the arteriovenous aneurysm demands immediate operation. However, when the aneurysm has not been operated upon before it reaches the evacuation hospital, and there is no immediate indication for interference, operation on the injured blood vessel should not be done sooner than from 4 to 6 weeks. This gives the surrounding tissues time for resolution of the bloody infiltration and for the development of the collateral circulation.

With reference to the type of operation, there is also a difference of opinion among surgeons. Some recommend vascular suture, which must of course be regarded as the ideal operation, while others prefer vascular ligation. However, in practice the former operation exhibits a number of complications which limit its theoretical indications. The author has carried out vascular suture in only 3 instances. Despite the fact that the author regards the technique of vascular suture as easier to accomplish than

is generally supposed, he sees no reason for regarding this procedure as the operation of choice. The character of his material has rather prejudiced him against vascular suture, both because so many of his patients showed infection of the wound with retention of devitalized tissues and foreign bodies and because so many of the blood vessel injuries resulted from the splinters of shells and bombs with extensive and irregular destruction of the wall of the blood vessel which rendered suture difficult. The method preferred by the author is that of Antilios or better of Phylagrus. The most radical, logical, and technically feasible method is that of Phylagrus, consisting of ligation of both the afferent and efferent vessels with complete extirpation of the sac. This extirpation is carried out as far as possible from every direction and with blunt dissection. However, occasionally a sharp instrument may be resorted to or in cases of too intimate adhesions, strips of the sac may be left *in situ*. When the operation of Phylagrus is anticipated an attempt is made to encourage the development of collateral vessels by putting pressure on the afferent vessels for 15 or 20 minutes twice daily. Extirpation of the regional sympathetic ganglia was done prophylactically in a number of instances. The operation is given enthusiastic support as a preventive of gangrene. In operation on the arteriovenous aneurysm the ligation of the vein together with the artery is believed to offer the best chance of avoiding the development of gangrene in the affected extremity.

Altogether, the vascular suture was carried out in 3 instances: the operation of Antilios in 89 and that of Phylagrus in 145. In the neck injuries the blood vessel was frequently injured so low in this region that partial resection of the clavicle and even of the chest wall was necessary. There were only 2 failures: the patient with the injury involving 3 vessels in the neck succumbed to a whole series of complications and gangrene developed in a patient with involvement of the leg. However, in the last instance the injury was complicated by a badly frozen foot.

JOHN W. BRENNAN, M.D.

Freeman, N. E.: Arterial Repair in the Treatment of Aneurysms and Arteriovenous Fistulas. *Ann Surg.*, 1940, 124, 885.

The author notes that the incidence of gangrene due to acute ischemia following operations on aneurysms and arteriovenous fistulas is rare. Not a single instance occurred in 100 cases operated upon at DeWitt General Hospital, Auburn, California. There was but one case in the entire series of patients in the three vascular centers of the U.S. Army. This splendid record is probably due to waiting a sufficient length of time for the development of collateral circulation and the perfection of surgical technique in order to spare the important collaterals. In addition

prophylactic sympathectomy may have helped practically to abolish gangrene after operations on arterial lesions.

The author discusses various objections to the arterial repair in the treatment of aneurysm and arteriovenous fistulas. Despite these objections to arterial repair an attempt was made to restore the continuity of the artery by repair in 23 cases of aneurysms and arteriovenous fistulas on the Vascular Surgical Section at DeWitt General Hospital between the months of June and November 1935. Success of the repair was demonstrable either by arteriography or by the presence of the normal arterial pulsations distal to the lesion in 18 of the 23 cases. The only complications which could be ascribed to the attempted repair were the possible recurrence of an arterial aneurysm in one patient and the recurrence of an arteriovenous fistula in another case after transvenous suture.

Detailed clinical experiences are presented with comments on 22 cases. Transverse repair of the artery was attempted in 17 cases and proved successful in 15. Of the 2 unsuccessful attempts thrombosis occurred at the suture line in 1 patient but this was due in part to faulty technique in not obtaining adequate control of the artery above the fistula. In the second individual, repair was attempted of an arterial aneurysm.

The author observes that it has generally been found desirable to use any sound portion of the arterial wall, even to one-sixth of the circumference, rather than to perform a complete transection with end-to-end anastomosis. Mobilization of the artery may be impossible because of important arterial branches. In no case was a significant collateral artery sacrificed in order to attempt repair of the major vessel.

Complete control of the arterial supply to an arteriovenous fistula is essential for repair. Arteriography has been helpful in the study of patients with arteriovenous fistulas. Before operation it has served in the accurate localization of the lesion and in demonstrating the location of important collateral vessels. Again, it has helped to show the presence of an aneurysmal sac. Following operation, arteriograms have been useful in disclosing the true state of continuity of the artery.

The role of sympathectomy in the repair of arterial lesions is not clear. Thirteen of the patients in this series were treated by prophylactic sympathectomy before operation on the arterial lesion. Of this number two attempted repairs failed. Sympathectomy was not performed in 10 patients. Arterial thrombosis occurred in only one of these cases. It is possible that sympathectomy might have prevented arterial spasm. It is probable that a swift flow of blood prevents thrombosis at the suture line. Possibly sympathectomy may have promoted an increased volume flow of blood and in this way improved the chances of successful repair.

In conclusion the author notes that arterial repair was attempted in the treatment of 23 aneurysms and

arteriovenous fistulas. Success was demonstrable either by arteriography or by the presence of normal peripheral arterial pulsations in 18 of these attempts. In one patient recurrence of an arterial aneurysm was subsequently reported by the patient. In a second patient, recurrence of an arteriovenous fistula followed transvenous suture. Subsequent excision of the lesion was necessary. Thrombosis at the suture line occurred in 3 patients but the collateral circulation proved sufficient to prevent gangrene. Repair of the defect in the wall of the vein was performed on 18 occasions. Phlebography in 12 of the patients after recovery demonstrated the patency of the vein in 6 patients but in 6 other postoperative studies, showed the vein to be occluded. No instance of thrombophlebitis or pulmonary embolism was encountered. Transverse suture of the defect in the arterial wall after excision of the damaged portion has been found more satisfactory than longitudinal suture, end-to-end anastomosis, or transvenous repair. Marked improvement in pulsatile circulation in patients after repair of arterial lesions in comparison to a control group who were treated by quadruple ligation and excision of the arteriovenous fistula, has been demonstrated by oscillometry.

The functional capacity especially as shown by freedom from intermittent claudication is increased in patients when the continuity of the major artery to the extremity is preserved.

HENRY F. THURMAN, M.D.

Carroll W. W.: Venous Surgery. *Q. Bull. Northwest. Univ. M. School* 94, 20-373.

The patients considered in the present report are (1) those with varicose veins resulting from valvular incompetence and (2) those with cutaneous ulceration of the lower extremities due to venous stasis resulting from various causes.

The author notes that an appreciation of the fact that varicose veins due to valvular incompetence are primarily related to valvular deficiency in the femoral and iliac trunks, makes our search for pathological perforators more logical. Such perforating veins may be located in the thigh, the lower leg, or in the popliteal space. In the latter instance the vein involved is anatomically designated as the lesser saphenous vein. The records in this article show that the resulting reflux was manifest through the lesser saphenous system in 10 per cent of 300 consecutive extremities requiring surgical correction for varicose veins. The technique for the treatment of varicose veins of the saphenous vein is described in detail.

Ulceration of the skin of the lower leg related to long standing venous stasis is known to result in serious disability because of a failure to heal. Excision of the ulcer-bearing area and coverage of the saucerized defect with a free skin graft of intermediate thickness results in the elimination of the open wound and its attendant long-standing painful duration. Such patients are restored to a satisfactory capacity for work. The author reports complete "takes" in 21 out of 22 such instances without

was found usually at 5 hours after transfusion, and this finding is in agreement with the observations of others. Feces urobilinogen was considerably increased after old blood but not after fresh blood transfusions.

In 5 of 6 patients studied, it was apparent that an increased rate of destruction of blood must have taken place after the use of old blood compared with that following the use of fresh blood. It is thus evident that there is an increased extravascular destruction of red blood cells after transfusion of old blood, for there is a significant rise in the serum bilirubin and feces urobilinogen excretion after such a transfusion.

LEROY J. KUCHARSKI, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

D'Errico, G.: Primary Lymph Gland Tumors of Vascular Origin—Lymphangioma of the Abdominal Lymph Glands (I tumori primitivi linfoglandolari di origine vascolare)—A proposito di un caso di linfangioma delle linfoglandole addominali. *Riforma med.* 1946 60 393.

There is still a great deal of confusion in regard to primary tumors of the lymph glands, some authors going so far as to say that all lymph gland tumors differ radically from each other and cannot be grouped into classes. Anardi's classification is probably the best. He differentiates between tumors originating from the parenchyma, including lymphoblastomas, lymphocytomas, and lymphomas; tumors originating from the stroma, including fibromas, lipomas, angiomatous fibrosarcomas, and sarcomas; and tumors originating from the blood or lymph vessels, including endotheliomas, peritheliomas, and reticulomas. The cell characteristics of these different groups are discussed and attention is called to the fact that angoma is a mature and benign tumor while endothelioma is an immature and malignant tumor.

In view of this confusion the detailed description of individual cases seems worth while. A case is described in a girl of 13 whose illness began about 6 months before admission to the hospital with pallor, loss of weight, and extreme fatigue on slight exertion. After some months enlargement of the abdomen was noted with abdominal pain and diarrhea. Roentgen examination showed a tumor apparently at the hepatic flexure of the colon. Operation revealed a tumor of the size of a coconut at the hepatic flexure but not connected with the colon. Other round tumors varying from the size of a hazelnut to that of a large mandarin were scattered over the gastrocolic ligament with a few in the mesogastrium and omentum. They were removed and weighed altogether 1,300 gm.

Microscopic examination showed that the lymph gland tissue had been replaced almost entirely by tumor tissue angiomatous in structure. There were many newly formed vessels, the smaller ones consisting of a simple endothelial tube with the surrounding tumor cells resting directly on its walls. The histological picture of these interstitial tumor cells was the same as that of the endothelial cells of the capillaries and the cells probably originated from an extravascular proliferation of the endothelial cells. The larger vessels contained leucocytes, which showed that this tumor had originated from lymph vessels rather than blood vessels. The tumor very clearly originated from the lymph glands of the abdomen and not from any of the abdominal organs. The peripheral lymph glands and the lymph glands of the thorax were not involved. The tumor showed mixed characteristics of the endothelioma and the perithelioma.

Photomicrographs of the histological findings are given.

In spite of roentgen treatment the patient died a few weeks after the operation.

JOHN W. BRECKENRIDGE, M.D.

Leveton, A. L.: The Surgical Principles of Split Thickness Skin Grafting. *J B Surg* 946 28 6pp.

The author gives an excellent description of the use of the split thickness skin graft. There are many technical points of interest in his experiences with the preparation, application, and postoperative care of the graft.

Split thickness grafts can be used as follows: (1) in clean granulating surfaces; (2) over the yellow base left by the excision of granulations; (3) in extensive burns, crushing injuries, or avulsions, and in infections with loss of tissue, as soon as the granulating bed is clean; (4) over fresh raw surfaces, if subcutaneous tissues are still present in the floor of the wound; and (5) as an intermediate step before the application of a full-thickness graft in obliterating osteomyelitis cavities.

Obviously the thicker the split-thickness graft, the better the coverage and the less the shrinkage. When it is laid on a freshly denuded scar base, on periosteum, or in an area surrounded by tense skin shrinkage is less than if it is applied to a fresh raw surface or movable base. Should any question arise about the cleanliness of the recipient area, the surgeon would do well to err on the side of conservatism and choose a graft of lesser thickness rather than risk the loss of a split-thickness graft.

In about 3 hours the graft is firmly attached to the base by the formation of fibrin, and leucocytes and fibroblasts begin their invasion of the clot. In about 18 hours the endothelial buds arising from proliferation of the endothelium of the host of blood vessels begin to invade the graft. Reichert demonstrated

that the regeneration of small arteries across clean operative wounds occurs by the end of the second day; that veins and lymphatics become anastomosed by the end of the fourth day; and that the process is physiologically complete by the eighth day after operation. After the lapse of 2 or 3 months, the cellular infiltration disappears. The fibroblasts become mature compressed cells of fibrous tissue and lose their plump spindle shaped appearance. A layer of fat of variable thickness is now found to line the deep surface of the graft, permitting it to move freely over the underlying tissue.

Full normal sensation usually develops in free skin grafts. It is influenced by the amount of deep scar tissue that is left behind and depends upon the presence of sensory nerves in the area and on the thickness of the graft. The sensations of pain, temperature, and touch may develop as early as in 5 weeks or as late as after several months.

Concerning the use of the Padgett dermatome, the author outlines several points of technical interest. The drum, brush, and the donor site should be absolutely dry; no trace of moisture may be present. It is well to go over the drum and the skin with ether to assure the dryness of these areas. The blade is placed in the instrument with the bevel away from the drum, and held in place by the clamp. It has been the author's practice not to use the same blade more than three times without having it sharpened. Cold sterilization is advocated. The cement is not poured until it is ready for use; if poured too soon its volatile elements evaporate and the viscosity increases. The optimum viscosity of the cement is also a matter of importance. If too thick, ether should be added until the proper consistency is obtained.

On application of the adhesive the drum is held in the left hand with the back of the blade and the carriage resting on the operator's wrist. The brush should have fine bristles from 1/16 to 1/8 inch wide. The cement is applied to the drum in a thin layer with sweeping strokes. There must be no back and forth brushing; a thick layer of cement will dry unevenly and invite failure. The edge of the drum should be adequately covered with glue, as this is the edge at which the blade engages the skin. Good adhesion between the skin and the drum at this point is of the utmost importance. After application of the cement to the drum and while the drum is still being held in the left hand the donor site is painted with adhesive. The same precaution of smooth even application of the cement is observed. Drying can be hastened by gentle fanning with a folded towel. Failure of any steps necessary for the successful application and adherence of the cement to the drum and the skin calls for immediate cessation of the procedure, which must be started again from the beginning. This means that every vestige of cement must be removed from the drum and the skin. Should blood or moisture be present on the drum or the donor site, it is thoroughly removed and the area is dried by sponging with ether. The graft is not placed in saline solution before use but is merely placed in

the folds of a damp towel or the cut surface is folded on itself. If the graft were allowed to soak in a basin of saline solution, the serum in the endothelial spaces would be washed out, small amounts of natural adhesive agents would be removed and the take of the graft might be jeopardized. A solution of 0.5 per cent procaine, containing from 6 to 8 drops of adrenalin to the ounce is used to infiltrate the scar bed. The adrenalin assures a dry bed until the graft has been sewed into place and the compression dressing applied. If the area will permit a tourniquet is used and the adrenalin solution may then be omitted. Excision of the scarred area is now undertaken. This must be complete and the underlying normal tissue must be exposed. The area to be excised is outlined with gentian violet. 5 per cent brilliant green in alcohol, or Bonney's blue solution. Perfect hemostasis is obtained first, with the adrenalin solution or the tourniquet. A blood vessel that requires tying should be ligated with the finest silk obtainable and the knot cut short.

It has been the author's practice to leave the granulating tissue in place if it is of recent origin and short duration. If the ulcer is old and calloused it is advisable to remove the granulation tissue by sharp dissection—never by scraping—to the smooth yellow base which has a satisfactory blood supply. Strips of 3 per cent xeroform gauze are laid smoothly upon a large abdominal pad. The surgeon without loss of time, places the pad over the donor site. Firm pressure is maintained and the whole area is bandaged snugly with a bias-cut stockinette bandage.

Postoperatively the odor of suppuration or of pyocyanus infection or a persistent elevation of temperature should call for an immediate inspection of the graft. There is no adequate reason why the graft should not be inspected before the usually accepted 10 to 14 day period. There are definite advantages to inspecting the graft much earlier. If a small clot or a collection of serum or blood is present that area may be saved by timely incision for evacuation of such fluid. If the wound is an early traumatic or an aseptic surgical wound the graft is inspected on the sixth or seventh day. If it is a granulating wound the graft is inspected on the third or fourth day. If the patient is febrile the graft is inspected at an earlier date. Upon inspection of the graft in the first week, it may present a mottled appearance. Some areas or the entire graft may appear cyanotic. This is not to be interpreted as death of the graft but rather as incomplete vascularization and diffusion of the blood pigments. In such cases it is well to continue with moist dressings until all such discolorations disappear. Should the graft be dry pink and adherent to the base one may apply a layer of gauze (44 by 40 mesh) without wrinkles and impregnated with 3 per cent xeroform. Over this is placed a voluminous dry pressure dressing. This dressing is changed every 3 or 4 days for about 3 weeks. At the end of this period, all dressings are discontinued and 3 per cent boric ointment is applied to keep the graft and the surrounding skin soft. If there is any ques-

tion about the status of the graft during the immediate postoperative period, one should at once revert to wet voluminous pressure dressings.

C. FRED GOETTINGER, M.D.

Gordon Taylor G. and Patey D. H.: A Further Review of the Interinnominoabdominal Operation Based on 21 Personal Cases. *Brit J Surg* 1946 34 61.

The authors review 21 cases in which these drastic operations were performed by them in the past 23 years. They have also made a chart which summarizes briefly the 73 cases which have appeared in the literature since 1935. In their own group of patients, 6 died shortly after surgery, 7 lived from 13 weeks to 5 years before they died of a recurrence, 5 are still well 1 or 2 years after surgery, and 3 are well 7, 11 and 17 years after surgery. All patients had some type of sarcoma, the most common being spindle cell sarcoma or chondrosarcoma.

Several aspects of the technique are discussed. The usual anesthesia is spinal, 10 c.c. of 1 to 1500 nupercalno are combined with general anesthetics such as pentothal nitrous oxide, and ether. The patient is placed in the lateral position for the iliac, inguinal, pubic, and gluteal portions of the operation and on his back for division of the symphysis pubis. The Gigli saw is used for the bone section after division of the internal iliac artery and division of the psoas muscle have been accomplished. The external iliac artery is divided distal to the origin of the deep epigastric and deep circumflex iliac arteries to assure good vascular supply to the abdominal muscles. A catheter is in the urethra during and after surgery. Blood for transfusion is always available. The anus is kept out of the operative field by suturing cellophane or green protective over it. The procedure requires about an hour and ten minutes. In addition to the usual postoperative care, the patient is placed on a type of water mattress. Chemotherapy is used and the dressings are kept firm with elastoplast.

DANIEL RUTZ, M.D.

Bardley, S.: Resuscitation by Cardiac Massage. *N Zealand M J*, 1946 45 446.

The author reports the case of a 36 year old man who while being subjected to intravenous pentothal anesthesia for tooth extraction suddenly developed complete respiratory and circulatory paralysis. After 12 minutes of complete cardiac arrest spontaneous cardiac action was again resumed following transabdominal transdiaphragmatic cardiac massage combined with the intracardiac injection of adrenalin. Respiratory function returned and the patient lived 4 1/2 days. Autopsy disclosed severe diffuse cerebral damage.

Twenty-nine minutes of cardiac arrest appears to be the longest recorded interval after which spontaneous heart beats have been resumed. A case from the literature is reported in which artificial respiration and cardiac massage were carried on for 20 minutes before spontaneous heart beats were resumed.

the patient had a perfectly normal recovery. Thus under these conditions sufficient circulation may be artificially maintained to prevent serious brain damage. If following cardiac arrest the resumption of cardiac function, either by spontaneous action or by rhythmic cardiac massage occurs within 4 minutes recovery is to be expected, but if the interval of cardiac arrest is longer than 8 minutes recovery does not occur.

F. J. LEIDEMANN, JR., M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Moore, F. D., Peacock, W. C., Blakely, E., and Cope, O.: The Anemia of Thermal Burns. *Ann. Surg.* 94, 24: 81.

The following etiological agents have been described as causative of the anemia of burns: external blood loss from infected granulations; early destruction of red blood cells due to heat; increased fragility of red blood cells; destruction of red blood cells due to anti-A or anti-B agglutinins in plasma; and suppression of the regenerative activity of the bone marrow by burn toxins.

In the present study the authors measured the red cell mass by the injection of donor cells containing radioactive iron and quantitated the dilution or concentration of these cells by means of a Geiger counter. In this manner the selective destruction of donor and recipient cells was determined after a radioactive transfusion. By the injection of radioactive iron in the form of ferrous ammonium citrate failure of the latter to appear in the peripheral blood according to a normal predetermined pattern was used to measure bone marrow activity.

In 4 cases, studies were made of early hemolysis, internal red cell disappearance, peripheral blood correlation, radioiron utilization, reticulocyte response, and pigment excretion. False anemia due to hemodilution from increased plasma transfusions was distinguishable clinically by examination for the stage of edema formation or resorption, the urinary output, serum protein dilution, and indices of peripheral erythrocyte concentration. The latter conditions indicated the necessity of withholding fluids to enable renal excretion to complete edema fluid resorption.

The true anemia of burns was characterized as an anemia divisible into three stages. The first stage was associated with the trauma of the burn itself and the resultant initial hemolysis. Cell destruction under those circumstances was less than 1 per cent of the red cell mass. The second stage of anemia developed within 10 days of the injury. During this period as much as 250 c.c. of red cells were lost or destroyed daily. Following the latter there was often a short period of positive red cell balance. The third stage occurred in the third or fourth week, and was again characterized by a daily loss of 500 c.c. of blood. Significant amounts of blood were lost as a result of debridement, in the cutting of skin grafts, and through the open wound into the dressing, particularly during the separation of the burn slough.

Fig. 2. (Moore et al.) Radioiron utilization, peripheral blood findings, and red cell balance showing an early and late progressive anemia in an extensively and deeply burned patient (78 per cent total, 45 per cent third degree). The radioiron utilization (F-59 build-up) is shown diagrammatically. The first test done on entry showed little elaboration into peripheral erythrocytes, correlating with the relative lack of reticulocyte response about the thirtieth day marrow function had improved, evidenced by better iron utilization as well as increase of reticulocytes to 4 per cent. By the eighty-fifth day utilization was normal. The peripheral counts demonstrate an early profound anemia with relatively little reticulocyte response, followed about the thirty-fifth day by rise with reticulocyte increase coincident with massive transfusion. Thereafter nearly normal levels were maintained. The red cell balance shows an early massive red cell loss (internal destruction) followed by relative balance until about the fiftieth day when, for about 3 weeks, cell disappearance increased again. After this period slightly positive balance obtained. (Courtesy of J. B. Lippincott Co.)

Although penicillin was used to combat infection nevertheless there seemed to be a relationship between large open infected wounds and the true anemia of burns. Studies in radioiron utilization indicated suppression of bone marrow activity, disorders of iron metabolism, and delayed hemoglobin synthesis of both the hemin and globin fractions. The relationship of the alarm reaction to the anemia of burns may be a positive one, as suggested by the prolonged negative nitrogen balance and the negative potassium balance which were found in all but one case.

BENJAMIN G. P. SHAFER, M.D.

Connor, G. J., and Harvey, S. C.: The Pyruvic Acid Method in Deep Clinical Burns. *Ann. Surg.* 94, 24: 790.

The primary objective in the treatment of severe burns is the rapid closure of the burn wound since all physiological disturbances are traceable to the open condition of the wound. The main cause for delay in skin grafting after correction of peripheral vascular failure is associated with the time loss awaiting the

slough of dead tissue. The present report is devoted to a new chemical method for the local treatment of burns by the use of pyruvic acid which is intended to hasten the slough of burned tissue.

A stock or standard solution of pyruvic acid is made by the addition of 1 liter of distilled water to 7 c.c. of C.P. pyruvic acid to make a solution with a pH of 1.9. From the latter a paste is prepared by the addition of an 8 to 10 per cent volume of corn starch. The success of the surgical treatment of burns by this method is dependent upon the use of a thick layer of pyruvic acid paste in direct contact with the wound. A burn extending from the ankle to the leg ordinarily requires about 3,000 c.c. of paste and first, second and third degree burns can be treated under the same dressing and the same standard pyruvic acid paste. Preliminary cleansing and débridement of the wound are not done. Evaporation and drying of the paste should be prevented by the application of an impermeable retaining dressing of vaseline gauze. The first dressing is applied at any time but may be delayed during the phase of circulatory imbalance. The second dressing (first redressing) is made 2 or 3 days later in the same manner as previously. A characteristic feature of the wound at this time is the prominent demarcation of the dead tissue. At the third dressing beginning separation of the slough should be evident. The proper cleavage plane is sufficiently apparent so that further separation can be facilitated by section of the anchoring strands of dead connective tissue, and subsequent application of pyruvic acid paste will reach the remote areas of the burn.

In the present series 30 burn cases were treated with pyruvic acid paste. The slough separated from the margin to the center of the burn and was removable in large sheets. Living islands of skin survived. Large deep thermal burns were ready for grafting within 10 or 12 days after the initial application of the pyruvic acid paste. With the removal of the slough there was a clean vascular surface ready for immediate grafting.

BENJAMIN G P SHATTOFF M.D.

Meleney, F. L.: Penicillin in the Treatment of Established Surgical Infections. *Ann Surg* 1946, 124, 903.

The Subcommittee on Surgical Infections appraised the results of penicillin therapy as follows: (1) excellent, when response was obtained within 72 hours after the beginning of treatment, (2) good when response was obtained from 7 to 10 days after the beginning of treatment, and (3) questionable when the surgical procedure and associated therapy could have been the effective factors. In some cases the infection ran its usual course in spite of the use of penicillin. This classification was used by 6 groups of surgeons located in different parts of the country reporting on 1,000 cases of established surgical infections. In this group there were 744 cases treated with penicillin. The data obtained from the case reports were transferred to the McBee System punch cards from which the following conclusions became apparent:

Penicillin although of great benefit, was not a panacea. Favorable results were obtained in 65 per cent of the entire series of cases. Dramatic results were demonstrated in the patients receiving penicillin therapy for cellulitis and furunculosis. Unsatisfactory results followed its use in the treatment of empyema, burns, gas gangrene and actinomycosis. When the cases are grouped according to their severity: (1) acute, (2) chronic with acute exacerbation and (3) chronic, the impression is gained that penicillin is more effective in the acute than in the chronic cases. In the acute cases there is an important relationship between the character of the response and the time of the initiation of treatment. In this group of cases studied 662 of the patients had serious infections and 384 had already received some form of sulfonamide therapy with favorable effects in 65.4 per cent. By the use of penicillin surgery may be obviated in some types of surgical infections, while under other circumstances surgery is required in conjunction with penicillin to effect a cure. On the basis of results in relation to the methods of administration particularly significant was the large proportion of cases controlled by the local application of penicillin. The adequate dosage of penicillin is defined as that amount which will control the infection and get the patient well. Nevertheless it is directly dependent upon the number and vulnerability of the offending bacteria, the amount and penetrability of the infected tissue and on the degree with which the drug is absorbed and excreted. The author believes that a maximum of 320,000 units of penicillin per day represents efficient therapeutic dosage which need not be exceeded. The acuteness or chronicity of the surgical infection is related to the bacterial flora of the purulent exudate. In acute infections one species of organism is usually found while in chronic infections a mixture of organisms is recovered.

The bacterologic studies included a bacterial classification of species as aerobic or anaerobic identification and a determination of pathogenicity. The first 4 principal bacterial groups were listed as the hemolytic streptococcus, the coagulase positive staphylococcus, the gram-negative aerobic and nonspore-forming rods (*Escherichia coli*, *Aerobacter aerogenes*, *Pseudomonas pyocyaneus* and *Bacillus proteus*) and the *Clostridium welchii*. As a rule all of these groups were more frequently found in mixtures than in pure bacterial cultures. The largest percentage of excellent results was obtained in the pure staphylococcal infections. Aerobic cocci in pure culture responded favorably while the anaerobic cocci and rods yielded unfavorable results. In patients with septicemia from the hemolytic *Streptococcus* an excellent response was obtained in 87.5 per cent of the cases and similarly in 69 per cent of cases with *Staphylococcus aureus* septicemia. Analysis of the penicillin failures revealed them to be ascribable to resistant strains of staphylococci or streptococci, the insufficient or too late administration of penicillin, associated chronic debilitating disease (tuberculosis, diabetes or arteriosclerosis) and finally overconservatism in surgery.

BENJAMIN G P SHATTOFF M.D.

Nichols, D. R., and Herrell, W. E.: Streptomycin. *J Am. M. Ass.* 1946, 131: 300.

The antibiotic agent, streptomycin, appears to have a place in the treatment of certain important bacterial infections. With few exceptions, the degree of sensitivity of organisms to streptomycin, as determined by *in vitro* studies, can be used as an index of the probable effectiveness of the treatment with streptomycin.

Satisfactory concentrations of streptomycin can be obtained in the blood and urine following intravenous, intramuscular and subcutaneous administration. The antibiotic is not destroyed in the gastrointestinal tract and a large percentage of it can be recovered from the feces when it is given by mouth. After oral administration, however, streptomycin cannot be detected in significant amounts in the blood and urine of patients. Streptomycin may be administered locally. It also may be administered by means of intrathecal injection and it may be instilled into various body cavities. Streptomycin diffuses fairly readily throughout the body. It is excreted readily in the urine without evidence of a toxic effect on the kidney. The usual daily dose of streptomycin employed in the treatment of infections is 3,000,000 to 3,000,000 units (2 to 3 gm.).

From the analysis of the results obtained in the treatment of 101 patients who received streptomycin under the supervision of the authors, and from the analysis of the results obtained in an additional group of 88 cases, certain conclusions can be drawn.

Streptomycin appears to be of considerable value in the treatment of bacteremia owing to gram-negative organisms sensitive to its action.

Streptomycin is of definite but limited value in the treatment of infections of the urinary tract. Best results are obtained when the organism of infection is *Proteus vulgaris* or *Aerobacter aerogenes*. Good results may be obtained at times when the organism of infection is *Escherichia coli* or *Pseudomonas aeruginosa*. Intensive treatment for a short duration appears to yield the best results.

Meningitis owing to *Hemophilus influenzae* usually responds satisfactorily to streptomycin. Additional treatment in the form of sulfonamides and antiserum may be indicated for this infection. Streptomycin appears to be of greatest value in the treatment of tularemia. It appears to be of definite value in the preparation of patients for pulmonary resection. Temporary or permanent eradication of sensitive organisms from the tracheobronchial tree at times can be achieved by its use. Temporary symptomatic improvement may occur from the use of streptomycin in the treatment of osseous. At this time final statements cannot be made concerning the value of streptomycin in the treatment of pulmonary and extrapulmonary tuberculosis.

Included among the infections in which streptomycin has proved of doubtful value are typhoid and paratyphoid fever, undulant fever, osteomyelitis, peritonitis, and cholangitis.

Organisms at times may develop resistance to streptomycin with incredible rapidity. This has a tremendously important bearing on the clinical results obtainable following its use.

No serious uncontrollable toxic reactions have been encountered from the use of streptomycin in the cases herein reported. On the other hand, irreversible neurotoxic effects on the eighth cranial nerve may occur if treatment with streptomycin is prolonged.

Keefer, C. S., and Associates: Streptomycin in Infections. *J Am. M. Ass.* 1946, 33: 4, 70.

A study was made by 55 investigators of the results obtained with streptomycin in the treatment of 1,000 cases of various infections. The discussions of these cases are concerned with the overall results in the various groups. The infections selected were tularemia, hemophilus influenza infection, urinary tract infection due to gram-negative bacilli resistant to sulfonamides, typhoid salmonella infections, acute brucellosis infection with bacteremia, bacteremia due to gram-negative bacilli, bacterial endocarditis due to gram-negative bacilli and Friedlander's bacillus infection (*Klebsiella pneumoniae*). A study of tuberculosis was not made. The specifications for streptomycin which were made effective by the Food and Drug Administration of the Federal Security Agency on July 15, 1946 are given in full. The modes of administration, such as intramuscular injections, subcutaneous injections, intrathecal injections, oral administration and inhalations, are described. The distribution in the body fluids and the excretion is also described. The results of treatment in these series are summarized in tables.

Following the tabulation of each of the results the authors make comments regarding the treated cases. They agree that streptomycin is an extremely effective agent in tularemia and that it is by far the best therapeutic agent for the treatment of this disease. In cases of bacteremia it was apparent that streptomycin was important in controlling the infection and in reducing the fatality rate.

The prognosis in these cases, however, was determined to some extent by the severity of the local lesions and many factors, such as the age of the patient, the site and extent of the initial lesion, the species of infectious organisms, the presence of complications, and the duration of the infection, had to be taken into account in assessing the results of the treatment with streptomycin. In some cases it was difficult to evaluate the precise role of streptomycin in bringing about recovery as the number of cases remains so small.

More extensive studies of streptomycin in the treatment of tuberculosis of various organs are necessary. A long range program should be planned and the patients should be followed up for a minimum period of 5 years. From the experience which has accumulated so far it appears that a minimum period of from 3 to 6 months of treatment will be required and in some cases it will be necessary to treat patients for a longer time. Streptomycin has an inhibitive effect on the growth of the tubercle bacillus and since the exudative lesions do not progress while the patient is under treatment the agent should be helpful when it is combined with

seemed to be temporarily benefited but failed to reveal any improvement

in the blood oxygen
above the initial values after
50-50 nitrous oxide was ad

more marked fall in the blood oxygen slightly above the initial values after 50-50 nitrous oxide was ad-

The carbon dioxide values remained quite constant in each of the 4 arterial blood samples from dogs but showed a slight rise in those from patients, after the administration of pentothal. When 50-50 nitrous oxide was administered with pentothal the amount of pentothal required to maintain the same plane of anesthesia was only one-fourth of that necessary when pentothal was used alone or with oxygen.

The addition of oxygen or nitrous oxide oxygen to pentothal for anesthesia produces a definite increase in the blood arterial oxygen values. MARY KARP MD

Beecher H. K.: Resuscitation and Anesthesia. *Aesthesiology* 946 7 644.

The author's study is based on experience with resuscitation and anesthesia during World War II.

Every effort is directed toward a single aim that of presenting to the surgeon a patient who will be as favorable an operative risk as possible. Several principles that are basic have emerged from, or have been tested in the present conflict.

1. Reduction in the time from wounding to surgery means the saving of extremities, the minimizing of deformity, the shortening of convalescence and the saving of lives. Every effort is bent toward reduction in evacuation time.

2. Economy of materials of time, and of lives will be effected by preventing serious deterioration of the patient's condition.

3. Once rapid restoration of good blood color and a systolic blood pressure to an arbitrary level of about 80 mm. of mercury have been accomplished the rate of infusion of blood or blood substitutes depends on several factors. (a) If blood for transfusion or operation will not be available for a matter of hours, infusion of plasma should be rapid enough only to maintain the aforementioned state. (b) If a patient must await surgery for a considerable period even though blood may be available, as long as the systolic blood pressure is not below a level of about 80 mm. of mercury the mucous membranes of good color, the skin warm, and the pulse of good quality there is no need to administer further blood until surgery is available. (c) when surgery is available further transfusion of blood is advisable so that a rising (or normal) blood pressure is achieved at the time the anesthesia is started.

4. Recovery from the damage produced by low blood pressure and by tissue anoxia probably requires many days. Practically it is necessary to initiate the surgical procedure long before the consequences of shock can be fully overcome. Operation is undertaken as soon as experience has shown that the patient will tolerate it, indicated chiefly by a rising blood pressure (80 mm.) or above, a falling pulse rate, a warm skin and good color of the mucous membranes.

5. Resuscitation, as it is usually thought of, is only supportive. Surgery alone checks the consequences of the wound.

Resuscitation includes all methods of management of the wounded man that make him, first, transport

able and then prepare him to meet the stress of essential surgery.

1. In the field, these methods are of the simplest order and have the single object of making the casualty transportable. (a) continuing hemorrhage must be controlled. (b) severe pain is the only important indication for the use of morphine, and when the relief of pain is urgent the intravenous route is the choice. (c) adequate immobilization of the wounded part particularly when skeletal injury is suspected, not only prevents further local damage but prevents shock. (d) food should not be given.

2. In the field or evacuation hospital the continuous service of one man in charge of resuscitation is desirable. General care in the preoperative ward includes (a) head-down position for all patients when the systolic blood pressure is falling or is below 80 mm. (b) the body heat of a wounded man is to be conserved by means of blankets. (c) oxygen therapy is instituted when cyanosis is present when the pulse rate is unduly high or when the wound itself may cripple cardiorespiratory function. (d) the administration of any fluid or food by mouth is generally contraindicated. Aspiration of vomitus is one of the most serious and common accidents to be encountered, and this may be precipitated by anesthesia. (e) glucose and saline solutions are useful only in the treatment of dehydration. (f) in the hospital where initial surgery is to be carried out one unit of plasma to about three blood transfusions has been found desirable in preparing for and carrying badly wounded patients through operation.

The seriously wounded need very little premedication, and morphine should be avoided in most cases. Atropine is useful to decrease the flow of mucus under ether and to minimize vagal reflexes. When local anesthesia is to be employed, if pain and considerable discomfort are to be anticipated, morphine may be used.

Three agents fulfill all of the important requirements of military surgery: ether, sodium pentothal, and procaine hydrochloride.

Ether has clearly emerged as the agent of choice for the seriously wounded, for the man in bad condition, and for long operations.

Acceptable practice in the employment of sodium pentothal includes the use of a 5 per cent solution, the routine administration of oxygen with it, and frequent observation and recording of pulse rate and blood pressure levels. A method of reducing the total quantity of sodium pentothal used is to supplement the agent with 50 per cent nitrous oxide and 50 per cent oxygen. Sodium pentothal is useful for 30 to 45 minutes, or less, of anesthesia in the lightly wounded and when employment of a noninflammable agent is imperative. Spinal anesthesia has few indications in surgery in forward areas.

Intratracheal intubation under general anesthesia is especially desirable for intracranial, maxillofacial, thoracic, and abdominal surgical procedures, and in other cases when the position of the patient makes it difficult to maintain a good airway.

The routine use of postoperative bronchoscopy even in open thoracic cases is undesirable

MARY FRANCES POT, M D

Frankson C. and Gordh T: Headache after Spinal Anesthesia and a Technique for Lessening Its Frequency *Acta chir scand* 1946 94 443

One of the most common and important complications of spinal anesthesia is the headache which sometimes occurs after operation. In most tabular summaries the incidence is between 15 and 30 per cent and most common in female patients younger than 40 years of age.

Two types of headache can be distinguished. One is characterized by increased intradural pressure—a rare type in which the ache is of a splitting character and does not react favorably to the patient lying in bed with the head end lowered. The second and more common type is characterized by a reduced intradural pressure. It is marked by a bandlike oppression in the forehead or nape usually aggravated by movement, and often combined with vertigo. It tends to diminish when the patient keeps quiet and lies with his head low. It is considered that the headache in such cases is caused by the reduced intradural pressure. This reduction in pressure may be caused by diminished production increased resorption or leakage of the spinal fluid. Changes in production and resorption may be precipitated by irritation caused by the anesthetic or the needle. To judge by the authors' investigation the chief cause that induces a headache or reduces the intradural pressure seems to be connected with the needle and puncture procedure that is, leakage of the cerebrospinal fluid into the epidural space. The authors have demonstrated that such leakage occurs and in some cases they have demonstrated that the dural puncture opening had been open for 2 weeks or longer. They believe that an attempt should be made to reduce the leakage at the puncture opening in the dura so that the ordinary puncture needles are too large diameter (from 0.7 to 0.9 mm.). They point out also the importance of the angle at which the point of the needle is held during the perforation of the dura and the importance of placing the beveled part parallel with the direction of the fibers of the dura with a greater tendency toward contraction. They contrast this with placing the beveled part at right angle to the longitudinal fibers whereby the fibers are cut off with a diminished prospect of closing the opening rapidly. They find by actual count that the number of fibers broken when the bevel is at right angles is twice that when the bevel is placed parallel to the fibers. They also find that the number of fibers torn off is directly proportional to the diameter of the needle. They believe that a relatively small opening is produced by a needle 0.5 mm. in diameter especially if beveling is placed parallel with the longitudinal direction of the dura fibers a finer needle causing less and less protracted leakage.

Fig. 1 (Frankson and Gordh) Sections in the plane of the dura after puncture. a, The beveling of the needle parallel with the longitudinal direction of the dura fibers; b, the beveling of the needle at right angles to the longitudinal direction of the dura fibers. Diameter of needle 0.5 mm (x 50)

Fig. 2 Sections in the plane of the dura after puncture. a, The beveling of the needle parallel with the longitudinal direction of the dura fibers; b, the beveling of the needle at right angles to the longitudinal direction of the dura fibers. Diameter of needle 1.0 mm (x 47)

The authors suggest the use of a fine needle (a special needle with introducer called Antoni Sise needle) of 0.5 mm. diameter. They describe the technique of inserting the 'introducer' first and then through this the fine needle. By this procedure they find that spinal anesthesia headache has been very considerably reduced and that no prophylactic measures regarding position are necessary.

G ALBIN LIVA, M D

Harmel M H., and Lamont A: Anesthesia in the Surgical Treatment of Congenital Pulmonic Stenosis. *Anesthesiology* 1946 7 477

The authors present an account of their experience in the administration of anesthesia in 100 patients

operated upon by Alfred Blalock for the relief of congenital pulmonary stenosis or atresia.

They state that the condition for which these patients undergo operation is, essentially, an insufficient flow of blood through the lungs due to pulmonary stenosis or atresia associated with the other stigmata of the tetralogy of Fallot with other congenital abnormalities and their sequelae. A compensatory polycythemia has developed and marked changes in the oxygen and carbon dioxide content of the arterial blood are found. It is obvious that most patients have a small cardiac reserve, and the physical activity is usually extremely limited.

The preanesthetic medication has usually been morphine and atropine given 90 minutes before the beginning of anesthesia, although on occasion nembutal instead of morphine has been used, or scopolamine instead of atropine. The authors like to have the patients so depressed that, if undisturbed, they will fall asleep. Venous cannulation and other painful or disturbing procedures are done after the induction of anesthesia.

The operation consists of making what amounts to an artificial ductus arteriosus by anastomosing one of the arteries arising from the arch to one of the main divisions of the pulmonary artery. Most of these patients seem to tolerate the partial collapse of one lung fairly well. Serious trouble, if it comes, more often starts when the anastomosis is begun, although not infrequently the exploration or even just the opening of the pleural cavity has been sufficient to weaken the action of the heart.

For induction, cyclopropane is usually chosen because it permits a rapid smooth induction and a high oxygen tension. Vinethene and nitrous oxide have also been successfully used.

For maintenance with the closed to-and-fro absorption technique, cyclopropane alone was used 56 times and ether alone was used 15 times. In 38 patients, a moderate amount of ether was added to the cyclopropane throughout the greater part of the procedure. Since the authors find it very much easier to provide a quiet operative field with cyclopropane they state that they are more likely to use that agent.

In the authors' experience the maintenance of positive pressure in the respiratory tract during both expiration and inspiration does not produce a sufficiently quiet field. The use of controlled respiration or of pressure on the breathing bag during the inspiratory phase of respiration better serves to maintain adequate tidal exchange and to relieve the patient of some of the muscular effort of breathing factors which are of some importance.

Although 6 cases were managed without the insertion of an endotracheal tube, the authors much prefer to use a tube. The endotracheal tubes always fit tightly enough without cuff or pack so that at the pressures employed there is no appreciable leak. For all of the cases when the closed technique was used a Foregger apparatus equipped with their water manometer has been employed. The manometer is set to blow off at 8 to 12 cm. of water pressure.

In the cases of most children, the induction proceeds at normal speed. There should be no hesitation in postponing the operation if there are any serious complications during the induction or if the patient does not react normally to the anesthetic agent.

A weakening of the cardiac action appears to be the commonest complication with either ether or cyclopropane. This complication occurred 5 times with ether 10 times with cyclopropane, and 15 times when both agents were used together. This complication was encountered in 42 per cent of the patients in whom the operation was on the right side, and in 24 per cent of the patients in whom the operation was on the left side. Whenever it occurs the operation is interrupted if possible, the retractor holding the ribs apart is released, and the lungs are reinflated.

The pulse rate varies considerably. There seemed to be no significant difference according to the agent used. The blood pressure also varies in no consistent fashion. The pulse pressure is usually reduced and has frequently been as little as 10 mm. of mercury. Minor cardiac arrhythmias, usually transient, have been noted in 12 anesthetics (11 patients). Respiratory complications during operation have not been very frequent. In 5 instances it was thought that bronchiolar constriction might have been present. Traction on the pulmonary artery has seemed to initiate the obstruction several times. Not infrequently when the anastomosis is opened there is a fairly sharp fall in both the systolic and diastolic pressure, with an increase in pulse pressure and pulse rate. The pressure usually rises again within 15 minutes. The tachycardia may persist for hours of days.

It is obvious that a successful anastomosis, when permitted to function, will immediately increase the flow in the pulmonary vessels and the work on the left side of the heart. It is surprising that these changes have not more frequently caused pulmonary edema and heart failure. Another possible complication resulting from the alteration in the hemodynamics is bleeding from the lungs. Sixteen patients have shown signs of interference with the flow of blood to the brain after operation.

As compared to the resting unanesthetized values, after 10 or 20 minutes of anesthesia the oxygen content, oxygen saturation and carbon dioxide content rose and the oxygen capacity fell. From 6 to 20 minutes after the operation had ended the oxygen content, the saturation, and carbon dioxide content were less than during anesthesia but still higher than before anesthesia, and the oxygen capacity was lower than during anesthesia. It is thought that a considerable rise in oxygen saturation which accompanies the administration of an anesthetic atmosphere rich in oxygen is an important factor in the ability of the patients to withstand operation.

Twenty three of the 100 patients died. The mortality rate was lower in those patients between 6 and 10 years of age. The duration of the operation appeared to have no influence on the mortality rate.

A larger proportion of the patients died when the innominate artery was selected for anastomosis. Fewer patients died when cyclopropane alone was used.

If those patients who received ether and cyclopropane together are grouped with those who received cyclopropane alone the combined mortality rate is not significantly different from the mortality rate in those patients who received ether alone for the maintenance of anesthesia. The authors believe that the hazards inherent in the physical condition of the patients and in the delicate operation have been of greater influence than the anesthetic factors.

MARY FRANCES DOE, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Jenkins, H. P., Senz, E. H., Owen, H. W. and Jampolis, R. W.; Gelatin Sponge for the Control of Hemorrhage. *J Am M Ass* 1946 132 614.

After a short survey of the work done by others and by themselves in the past concerning absorbable sponge-like hemostatic agents the authors report first a series of experiments on animals. In 23 dogs substantial parts of the liver were resected and the defects blanketed with gelatin sponge which was fixed with pressure for from 5 to 10 minutes. This controlled the hemorrhage. Two of the animals died later from biliary peritonitis. Studies of the healing showed that the sponge unlike foreign bodies in general appeared to promote the healing process.

Massive hemorrhage from wounds in the vena cava of 27 dogs could be controlled by a patch of gelatin sponge applied with finger pressure. The patch becomes endothelialized and the wall defect healed with an endothelialized scar within about 2 weeks. The fact that in 1 case a large mural thrombus was observed suggested the use of anticoagulants when one is attempting to stop massive venous bleeding by the use of gelatin sponge in human beings.

Rats in large arteries were patched similarly in dogs but a sheath of chromicized catgut was found necessary to prevent blowouts. In these experiments propagating thrombosis was encountered once.

Stab wounds of the heart were similarly treated and it was found that gelatin sponge patches held to such wounds for about 10 minutes became adherent and stopped the hemorrhage.

The gelatin sponge was used in 140 clinical cases and it was found useful on the liver after cholecystectomy and biopsy in thyroidectomy near the recurrent nerve in the abdomen after freeing of the adhesions in the chest after excision of the thickened pleura or removal of mediastinal tumors it was also found useful after biopsy of abdominal tumors. Furthermore it is useful in skin grafting on donor areas and after removal of granulations it can be used as packing after rectal operations as nose packing in recurrent nose bleeding and after tooth extractions.

Gelatin sponge is not supposed to be used when hemostasis by clamp and tie will work satisfactorily. It is mainly used at this time when these methods fail or when their use entails danger. It should also serve well as a first aid dressing.
